(Fig. 4) in comparison to standard *S*-process SL media at 136.4 KFCI recording density. Figure 5 depicts x-ray diffraction (XRD) spectra of SL media sputtered by *N* and *S* processes. The Co(11.0) peak was not recorded in wider angle scans (θ -2 θ :20°–80°) of these samples. Also, for both samples data taken at a shallow grazing angle of 0.3° indicated the presence of only two peaks: Co(10.0) and Co(10.1) and did not show Co(002) plane which means that the texture of these samples near 44° is due to Cr(110), not the Co(002). Among the CoCrTa/Cr peaks, the Co(10.0) and Co(10.1) peaks are stronger in *N* media when compared to *S* media, indicating a higher degree of preference for the *c* axis of CoCrTa to lie in or near the plane of the film and producing higher in-plane H_c . In addition, Co(10.1)/Cr(110) epitaxy of CoCrTa/Cr is more noticeable in the *N*-process media. This may be due to the higher deposition temperature for the magnetic layer during the *N* process. It has also been noted that the Co(10.1)/Cr(110) epitaxy is preferable to the Co(11.0)/Cr(200) epitaxy for reduction of intergranular exchange coupling.¹

B. CoCrTa/Cr/CoCrTa:ML media

Magnetic and recording properties of CoCrTa SL and ML media sputtered by *N* process are summarized in Table II. These data show that the H_c decreases slightly with no change in $M_r t$ and S^* for ML media with Cr-IL:10 Å in

FIG. 4. Normalized media noise and SNR as a function of linear recording density for CoCrTa/Cr:SL media (magnetic film thickness: 190 Å) sputtered by *N* vs *S* processes.

FIG. 5. X-ray diffraction patterns of CoCrTa/Cr:SL media (magnetic film thickness: 190 Å) sputtered by (A) *N* and (B) *S* processes.

comparison to SL media. Comparison of recording characteristics: HF amplitude, pulse width (PW-50), overwrite (OW), bit shift (BS), and SNR at 68.2 KFCI recording density for SL and ML media with comparable H_c and $M_r t$ showed superior performance for ML media. ML-media sputtered in single chamber produced higher HF amplitude, lower PW-50, better OW, lower BS. In the case of conventional ML media, the OW degrades due to higher write field needed to satisfy the mean switching field of the media with the lower S^* .⁸ Further, to compare the noise characteristics of these SL and ML media, normalized media noise and SNR as a function of recording density were measured and are illustrated in Fig. 6. It was observed that the ML media with Cr-IL:10 Å produced ~29% lower media noise and ~4 dB higher SNR at 153.4 KFCI recording density in comparison to SL media. It has been shown that the Cr-enriched grain boundaries with Cr-IL:5–15 Å thickness might be enough to reduce the exchange coupling between the upper and lower magnetic layers.^{4,5,9} Also, a thinner Cr interlayer is helpful in reducing the head-media spacing loss which affects the recording performance.

IV. CONCLUSIONS

SL media fabricated by *N*-process produced ~400–600 Oe higher H_c , ~24% lower media noise and ~3 dB higher

TABLE II. Comparison of magnetic and recording properties of CoCrTa:SL vs ML media (magnetic film thickness: 190 Å) sputtered by *N* process.

Media type	Cr IL (Oe)	H_c (Oe)	$M_r t$ (memu/cm ²)	S^*	HF (uV)	PW-50 (nS)	OW (-dB)	BS (nS)	SNR (dB) at 68.2 KFCI
SL media	0	2210	1.1	0.77	1177	33.6	41.2	4.8	24.1
ML media	10 Å	2075	1.1	0.76	1213	31.6	41.8	4.2	26.9

FIG. 6. Normalized media noise and SNR as a function of linear recording density for CoCrTa:SL vs ML media (magnetic film thickness: 190 Å) sputtered by *N* process.

SNR at 136.4 KFCI recording density in comparison to *S*-process SL media. XRD of *N*-process SL media showed strong preferred orientation indicating high number of grains with their *c* axis in or near the film plane producing high in-plane H_c . Due to zero dwell time, the interfacial structure and chemistry for the epitaxial growth of Co-alloy film produced lower transition noise, possibly due to enhancement in Cr segregation at grain boundaries. ML media fabricated by *N*-process showed no reduction in $M_r t$ and S^* , and exhibited superior read/write characteristics in comparison to SL media. In summary, the new composite-target cathode process eliminates the heat loss in between the deposition layers, improves the magnetic and recording performance, approaches superparamagnetic state at a maximum H_c with lower $M_r t$ for high density recording, and reduces the number of sputtering chambers and targets required to fabricate SL and ML media in production.

The media noise performance is discussed in connection with grain size and intergranular coupling for the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$, $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$, and $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ thin-film media fabricated under the ultraclean sputtering process (UC process). It is clarified that the value of S/N_m is quantitatively represented as functions of the value of H_c/H_k^{grain} and the grain size in every kind of media. The value of signal-to-media noise ratio (S/N_m) increases with the increment in H_c/H_k^{grain} and also with the decrement in grain size. In the media with grains adequately separated by segregated grain boundaries fabricated by the UC process, grain-size reduction, taking account of the decrease in intergranular magnetostatic coupling, is required to obtain even higher S/N_m values. © 1996 American Institute of Physics. [S0021-8979(96)09608-9]

I. INTRODUCTION

Low media noise is essentially required for thin-film media to achieve high-density magnetic recording. The decrement of intergranular exchange coupling and grain-size reduction are generally suggested to be essential factors to decrease media noise,¹ but quantitative evaluation concerning the effects of grain size and intergranular coupling on media noise has not been experimentally clarified.

An ultraclean sputtering process (UC process) is proposed to be a key technology to enable the enhancement of Cr segregation at grain boundary resulting in low intergranular exchange coupling.^{2,3} Furthermore, by decreasing underlayered Cr thickness, the UC process realizes the reduction of ferromagnetic grain size without the increment of intergranular exchange coupling.

In the present study, dependence of recording properties on Cr thickness was examined for thin-film media fabricated under the UC process. The media noise performance is discussed in connection with grain size and intergranular coupling.

II. EXPERIMENTAL PROCEDURE

The thin-film media were fabricated under the UC process with a specialized production-type sputtering machine (ILC3013 ANELVA) and ultraclean Ar gas (UC-Ar). The base pressure of each process chamber is less than 3×10^{-9} Torr and the buildup rate is less than 5×10^{-7} Torr/°s. The impurity level of UC-Ar is about 1 ppb (H_2O level) at the point of use.

In this study, $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$, $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$, and $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ targets with low impurities were used for the magnetic alloys. The films were deposited on extremely smooth nontextured (Ra below 1 nm) NiP/Al substrates with underlayered Cr films. The value of tB_r (the product of film

thickness and remanence) was fixed at 100–120 G μm , which corresponds to thicknesses of about 16 nm in $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$, 28 nm in $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$, and 13.5 nm in $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$. The underlayered Cr thickness was varied from 2.5 to 100 nm. The substrate temperature was kept at 250 °C during the film deposition. The dry-etching time of substrate surface just prior to film deposition⁴ was fixed at 0 or 10 s, which corresponds to 0 or about 0.2 nm in etched depth.

The recording characteristics were evaluated by using a magnetoresistive head. The thin-film media were dc erased prior to the evaluation of the recording characteristics. The signal frequency was 16.8 MHz. The linear velocity was 12.2 m/s. The spacing between the head and the media was 0.08–0.10 μm . The media noise was measured using a spectrum analyzer and calculated by integrating the readback noise spectrum from 0 to 33.6 MHz.

III. RESULTS AND DISCUSSION

In Fig. 1, the values of readback S/N_m at 69.7 k FCI in $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$, $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$, and $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ media are plotted against the thickness of Cr underlayer. These media were fabricated onto the substrate surface with dry-etching treatment.

In the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$ and $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$ media, S/N_m gradually increases with decreasing Cr thickness, and shows highest values at extremely thin Cr thicknesses of about 2.5–5 nm. This increase in S/N_m with decreasing Cr thickness was mainly caused by the decrement in media noise. On the other hand, even in the $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ media, high S/N_m is realized by applying the UC process due to the remarkable decrement in media noise.³ However, S/N_m in this media gradually decreases with decreasing Cr thickness especially from about 10 nm in thickness.

FIG. 1. The values of S/N_m at 69.7 kFCI in $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$, $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$, and $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ media (fabricated onto the substrate surface with dry-etching treatment) plotted against the thickness of Cr underlayer.

In Fig. 2, the values of coercive force H_c in these media are plotted in the similar way. Here, H_c of these media is isotropic in the film plane.

H_c in both the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$ and $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$ media shows almost a constant value of about 2.3 kOe through 10 nm in Cr thickness. With further decreasing Cr thickness, H_c in both media drastically decreases. However, H_c in the $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$ media maintains its large value of about 2.1 kOe at even 2.5 nm in Cr thickness. On the contrary, H_c in the $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ media decreases gradually from 2.6 to 0.8 kOe with decreasing Cr thickness from 100 to 2.5 nm. Cr thickness dependences of S/N_m in Fig. 1 are found not to correspond simply to those of H_c , especially in the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$ and $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$ media.

In order to discuss the effect of the degree of intergranular coupling on media noise, in Fig. 3, the values of H_c normalized by H_k^{grain} in these media are plotted in the simi-

FIG. 2. The values of coercive force H_c in the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$, $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$, and $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ media (fabricated onto the substrate surface with dry-etching treatment) plotted against the thickness of Cr underlayer.

FIG. 3. The values of H_c normalized by H_k^{grain} in the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$, $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$, and $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ media (fabricated onto the substrate surface with dry-etching treatment) plotted against the thickness of Cr underlayer.

lar way. Here, H_k^{grain} was evaluated from the magnetic field where rotational hysteresis loss just vanishes.⁵ The value of H_c/H_k^{grain} means the degree of intergranular coupling of magnetization, and takes the ideal maximum of about 0.5 in the case of isotropic media with no intergranular coupling.

In both the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$ and $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$ media, H_c/H_k^{grain} maintains its large value more than 0.37 through 10 nm in Cr thickness. With further decreasing Cr thickness, the value of H_c/H_k^{grain} in the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$ media drastically decreases. However, in the $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$ media, a large value of about 0.35 is retained even at 2.5 nm in Cr thickness. This result implies that, in the $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$ media, extremely low intergranular coupling is realized with an extremely thin Cr underlayer. On the other hand, large H_c/H_k^{grain} values are realized even in $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ media, which means the realization of low intergranular exchange coupling due to the enhancement of Cr segregation at grain boundaries.³ However, the value of H_c/H_k^{grain} in the $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ media gradually decreases with decreasing Cr thickness. In the thinner Cr region, the values of H_c/H_k^{grain} in the $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ media are adequately smaller than those in both the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$ and $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$ media.

In the $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ media, the decrease in S/N_m with decreasing Cr thickness is found to correspond qualitatively to the increase in intergranular exchange coupling. However, S/N_m in both the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$ and $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$ media gradually increases in spite of the decreasing in H_c/H_k^{grain} with decreasing Cr thickness.

It should be noted here that, even in the media with grains sufficiently separated by the segregated grain boundaries, grain-size reduction is suggested to increase the intergranular magnetostatic coupling due to the increment in the number of magnetically coupled grains. In every media presently examined, grain size strongly depends on Cr thickness. In both the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$ and $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$ media, the grain size markedly decreases from about 25 nm to about 11 nm with decreasing Cr thickness from 50 to 2.5 nm. Therefore, in present media, precise discussion is possible for the cor-

FIG. 4. The values of S/N_m at 69.7 k FCI in $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$ and $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$ media plotted as functions of H_c/H_k^{grain} and grain diameter.

relation between intergranular coupling and S/N_m from the viewpoint not only of the degree of grain separation at grain boundaries but also of the grain size.

In Fig. 4, the values of S/N_m in both the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$ and $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$ media fabricated under several fabrication conditions (with and without dry-etching treatment) plotted as functions of H_c/H_k^{grain} and grain diameter.

As seen, it is clearly found that S/N_m increases with the increasing in H_c/H_k^{grain} . Furthermore, with the reduction of the grain diameter, S/N_m remarkably increases in both media. That is to say, S/N_m increases not only with the decrease in intergranular coupling but also with the reduction in the grain size.

In Fig. 5, the values of S/N_m in the $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ media

FIG. 5. The values of S/N_m at 69.7 k FCI in $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ media plotted as functions of H_c/H_k^{grain} and grain diameter.

fabricated under several fabrication conditions (with and without dry-etching treatment) are plotted as functions of H_c/H_k^{grain} and grain diameter.

The S/N_m of the $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ media shows similar dependence on the H_c/H_k^{grain} and grain diameter as those in both the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$ and $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$ media.

These experimental results shown in Figs. 4 and 5 mean that S/N_m of thin-film media can be quantitatively discussed as functions of the intergranular coupling and the grain size. In the media with grains adequately separated by segregated grain boundaries, the reduction of the grain size is effective for the improvement of S/N_m . Furthermore, the increase in H_c/H_k^{grain} value through the decrease in intergranular magnetostatic coupling is found to be essential in order to realize even higher S/N_m values in these media. For the decrement in intergranular magnetostatic coupling in these media, the selection of alloy composition, which gives a small ratio of saturation flux density $4\pi M_s$ to H_k^{grain} , is suggested to be the most important factor.⁶

IV. CONCLUSIONS

The media noise performance is discussed in connection with grain size and intergranular coupling for the $\text{Co}_{85.5}\text{Cr}_{10.5}\text{Ta}_4$, $\text{Co}_{78}\text{Cr}_{17}\text{Ta}_5$, and $\text{Co}_{62.5}\text{Ni}_{30}\text{Cr}_{7.5}$ thin-film media fabricated under the UC process.

As a result,

(1) The value of S/N_m is quantitatively represented as functions of the value of H_c/H_k^{grain} and the grain size in every kind of media. The value of S/N_m increases with the increment in H_c/H_k^{grain} and also with the decrement in grain size.

(2) In the media with grains adequately separated by segregated grain boundaries fabricated by the UC process, grain-size reduction, taking account of the decrease in intergranular magnetostatic coupling, is required to obtain even higher S/N_m values.

The role of stress-induced anisotropy in longitudinal thin film magnetic recording media

C. A. Ross, M. E. Schabes, R. Ranjan, G. Bertero, and T. Chen
Komag Inc., 275 S. Hillview Drive, Milpitas, California 95035

Measurements of stress and magnetostriction have been made in longitudinal CoCrTa magnetic recording media. The stress in Cr and CoCrTa/Cr films deposited onto grooved substrates is higher parallel to the grooves compared to perpendicular to the grooves by up to a few hundred MPa. Combined with a magnetostriction coefficient of -3×10^{-5} in CoCr₁₀Ta₈/Cr, magnetostriction makes a contribution to the in-plane anisotropy observed in such media. © 1996 American Institute of Physics. [S0021-8979(96)15408-2]

I. INTRODUCTION

Longitudinal magnetic recording media are typically made by sputtering a Cr underlayer, Co alloy magnetic layer and C overcoat sequentially onto a heated nickel phosphorus-coated aluminum substrate which has been circumferentially textured or grooved. It is commonly observed that the magnetic film has higher coercivity, remanence and squareness in the in-plane circumferential direction compared to the radial direction. The ratio of circumferential to radial coercivity is known as the coercivity orientation ratio, OR_{Hc} . Several explanations have been proposed for this in-plane anisotropy, including magnetostrictive effects caused by in-plane stress differences.¹⁻⁴ Despite some modeling,⁵ the theory for texture-induced magnetic anisotropy remains incomplete. In this article we explore the importance of stress-induced anisotropy by measuring stress and magnetostrictive effects in CoCrTa/Cr media.

II. EXPERIMENTAL METHODS

Samples were made by dc magnetron sputtering of Cr and Co alloy films in an Intevac 250 A system onto 3 cm \times 3 cm \times 0.8 mm coupons of smooth and textured nickel-phosphorus coated aluminum substrate. The coupons were preannealed at 250 °C for 2 h in air to stabilize them against warping during high temperature processing. The curvature of the coupons was measured in two perpendicular directions, parallel and perpendicular to the grooves, using a profilometer, both before and after film deposition. The stress in the films was calculated from the change in curvature of the coupons, taking account of the nonuniform biaxial stress state. Changes in curvature due to 100 nm thick films were typically 100–200 nm over a 20 mm scan length. The aim of the experiment was to use real disk substrates, rather than glass or silicon substrates, so that the microstructure of the films would be the same as found in recording media. However, the relatively high thickness of the substrates necessitated deposition of 75–100 nm thick films to obtain adequate sensitivity in the stress measurement.

Magnetostriction was measured in a torque magnetometer using a fixture similar to that of Mauri *et al.*⁶ Samples of size 8 mm \times 5 mm were cut from sputtered disks and the pieces were thinned to 0.5 mm from the back by milling. The film was removed from the ends of the sample so that a 4 mm \times 5 mm area of Cr/Co alloy film was left at the center of

the sample. The fixture applied a variable biaxial stress to the film by a three point bending of the sample. The actual stress applied during each measurement was deduced by measuring the curvature of the 4 mm \times 5 mm area of film using a profilometer. The fixture applied a plane biaxial stress to the sample which was much higher along the direction of bending compared to the perpendicular direction. The applied stress $\Delta\sigma$ was taken as the difference between the two in-plane stress components. In-plane anisotropy K was measured as a function of applied stress, and magnetostriction λ was calculated from the change in anisotropy, ΔK with stress from the relation $\Delta K = -3/2\lambda\Delta\sigma$. Magnetostriction was measured at low applied stress where deformation was still elastic.

III. RESULTS

A. Stress in Cr and CoCrTa films

Stress was measured in 100 nm thick Cr films sputtered at 20–200 °C onto smooth and textured substrates. Figure 1(a) shows clearly the effect of the substrate grooving in Cr films. The stress is 1.4 times smaller perpendicular to the grooves compared to the stress parallel to the grooves. In contrast, the stress in films on mirror polished substrates was always isotropic and similar to the stress parallel to the grooves in the textured samples.

The sputter system has circular symmetry and the substrates were not moved during deposition, so stress anisotropy might be caused by the geometry of the sputter system. However, orienting the grooves in different directions had no effect on the stress, showing that the stress difference originates from the substrate texture. Figure 1(a) shows that the film stress decreases as the substrate temperature increases. As the sample cools from the sputter temperature, a compressive thermal mismatch stress is added to the intrinsic stress in the film.

Stress in CoCrTa films on a chromium underlayer were estimated by depositing bilayer samples with a 25 nm chromium layer and 75–100 nm CoCrTa and subtracting the contribution of the Cr stress to the curvature, calculated from the results on the 100 nm Cr films. This assumes that the stress in the Cr layer is independent of thickness, and more importantly, it neglects changes in the stress in the Cr caused by epitaxial growth of the Co overlayer. As a result of the Cr subtraction, the results for stress in CoCrTa on Cr show

FIG. 1. Stress in films measured parallel and perpendicular to the texture lines. (a) Cr on smooth and textured substrates; (b) CoCrTa on a Cr underlayer, in which the Cr contribution has been subtracted. Points are joined for clarity.

greater scatter than results for a single Cr layer. Figure 1(b) shows that the stress in the CoCrTa layer becomes compressive as substrate bias is applied, due to greater bombardment of the film during growth. Stress was generally smaller perpendicular to the grooves, an effect similar to that found in the single Cr films. The maximum in-plane stress difference measured in the CoCrTa was 300 MPa over a range of deposition conditions.

The total stress consists of a thermal component, which becomes more compressive as deposition temperature increases, and an intrinsic component. The temperature dependence of total stress in the CoCrTa was found to be small, indicating that the intrinsic stress in the CoCrTa becomes more tensile at higher deposition temperature, due to changes in grain size, crystal orientation, and segregation of the alloying elements.

B. Effect of applied stress on in-plane magnetic anisotropy

Figure 2 shows the in plane anisotropy as a function of applied tensile stress for CoCrTa/Cr samples deposited at different substrate temperatures. In these samples the

FIG. 2. Effect of applied stress on in-plane anisotropy of CoCrTa/Cr films deposited at different temperatures.

CoCrTa and Cr films were 40 nm thick, typical of hard disk media, and thinner than the samples used for stress measurements. Tension was applied parallel to the texture lines. The abscissa shows the tensile stress difference between the two principal directions of stress in the film plane. Hysteresis loops were also measured for these samples and showed that tensile stress lowered the coercivity parallel to the tensile axis and raised it in the perpendicular direction. This is characteristic of a negative magnetostriction coefficient.

Applying a tensile stress parallel to the grooves made the textured samples less anisotropic. In comparison, films on smooth substrates developed in-plane magnetic anisotropy as the applied stress increased. The magnetostriction coefficient λ was measured from the data taken at low applied stress. In CoCr₁₀Ta₆/Cr deposited on a textured substrate, magnetostriction increased with deposition temperature, from -4×10^{-6} at 20 °C to -26×10^{-6} at 200 °C and -34×10^{-6} at 250 °C. For the same samples, OR_{Hc} increases from 1.0 to 1.6 with increasing substrate temperature. The difference in λ between films made on heated versus unheated substrates reflects differences in crystal orientation and microstructure. The Cr has a (110) orientation when sputtered onto an unheated substrate so the Co grows with a significant c -axis out of plane component. This is expected to change the measured λ ,⁷ as will composition differences in the Co due to differences in grain boundary segregation. CoCr₁₇Pt₁₂/Cr deposited onto a textured substrate at 200 °C had $OR_{Hc}=1.3$ and $\lambda=-8 \times 10^{-6}$.

IV. DISCUSSION

Our stress measurements showed that stresses were higher parallel to the grooves in films on textured substrates. The torque experiments demonstrate that a stress applied to a magnetic film leads to an in-plane anisotropy in which the more compressive (or less tensile) direction becomes the direction of higher coercivity in a material with negative magnetostriction. This mechanism, combined with the observed

stress differences in textured samples, leads to a stress-induced contribution to the magnetic anisotropy of oriented media.

The magnitude of the anisotropy is proportional to both the magnetostriction coefficient and the in-plane stress difference between directions parallel and perpendicular to the texture lines. Samples with low magnetostriction, such as those sputtered on unheated substrates, will have low stress-induced magnetic anisotropy even if the in-plane stress is anisotropic. The commonly observed increase in magnetic anisotropy with deposition temperature may be partly related to the measured increase in magnetostriction, and increases in magnetic anisotropy⁸ with substrate bias to changes in in-plane stress difference.

These measurements show that stress parallel to the texture lines exceeds stress perpendicular to the texture lines by up to 300 MPa in thick films of CoCrTa on Cr. The CoCrTa films in this study were in compression. A stress difference $\Delta\sigma$ of 300 MPa, coupled with a magnetostriction coefficient of -26×10^{-6} for the 200 °C sample leads to stress-induced magnetic anisotropy $K_\sigma = (3/2)\lambda\Delta\sigma$ of 1.2×10^5 ergs/cm³. The total anisotropy K_{tot} was 8×10^5 ergs/cm³, a value similar to one reported elsewhere for CoCrTa/Cr media with a textured substrate.²

These calculations show that if $\lambda = -26 \times 10^{-6}$, stress-induced magnetic anisotropy can account entirely for total in-plane anisotropy only if an in-plane stress difference much greater than 1000 MPa exists in the film. X-ray measurements by Kawamoto and Hikami² gave an in-plane strain corresponding to a stress difference of up to 1200 MPa, taking Young's modulus of 200 GPa, but other measurements by x-ray diffraction indicate smaller in-plane stress differences of 300 MPa (Ref. 1) or 200–400 MPa (Ref. 9). Of these, only Kawamoto's samples² have sufficient in-plane stress difference to account entirely for K_{tot} . The curvature method used here in its present form is insufficiently accurate to measure stress in the thinner 20–40 nm films used in current media, and it is also limited by the need to subtract the effect of the Cr layer. The method gives an average stress, and does not indicate small scale stress fluctuations near features such as texture lines. Additional measurements indicate that the stress, and presumably the in-plane stress difference, in thinner films is greater than the stress in the thick films reported here.

The nonuniform biaxial stress observed in the films on grooved substrates originates during topographically induced anisotropic growth of the crystals or by relaxation at structural discontinuities within the film, caused for instance by shadowing at texture valleys. A finite element calculation of stress in strips of film separated by discontinuities, Fig. 3, shows that as the aspect ratio (the ratio of distance between discontinuities to film thickness) decreases, the stress perpendicular to the grooves decreases.¹⁰ With an aspect ratio of 9, the stress parallel to the grooves exceeds that perpendicular to the grooves by a factor of 1.4 as seen in the Cr. Differential stresses can exist even if the film discontinuities are very narrow. Stress relaxation at the tops of texture ridges¹¹ is of minor importance since in a typical texture the surface

FIG. 3. Calculated stress ratio in a discontinuous film on a textured substrate for different a/d ratios, where d represents film thickness and a represents the distance between film discontinuities.

angles are generally no more than a few degrees, and finite element calculation of stress in a continuous film deposited on such a substrate shows negligible stress relaxation over the relatively smooth topography.

V. CONCLUSIONS

Measurements of stress in 75–100 nm Cr and CoCrTa films deposited over grooved substrates show a greater stress parallel to the grooves compared to the stress perpendicular to the grooves. The stress is compressive in films made at high substrate biases and substrate temperatures, and the in-plane stress difference can reach a few hundred MPa. The magnetostriction coefficient of 40 nm CoCr₁₀Ta₉₀/Cr films deposited at 200 °C was measured as -26×10^{-6} . Combined with the in-plane stress difference, stress-induced anisotropy provides a contribution to the in-plane anisotropy of films deposited onto textured media. Anisotropy is low in films with low magnetostriction, such as CoCrTa/Cr on a cold substrate. Further measurements are underway to resolve the differences reported in the x-ray strain data from the literature.

Polarization dependent extended x-ray absorption fine structure (PD-EXAFS) and magnetic circular dichroism (MCD) measurements of CoCrTa and CoCrPt films, sputter deposited at varying substrate temperatures, were performed to investigate the average local structure and chemistry about the Ta, Pt, and Co atoms and the average magnetic moment of the Co and Cr atoms within these films. Results from the MCD measurements indicate the average net magnetic moment of the Cr atoms is opposite in direction and five percent in amplitude relative to the Co moments. Inspection of the Fourier transforms of the XAFS data from these samples shows an increase in structural disorder around the Ta and Pt atoms with increasing substrate deposition temperature. A further comparison between the Ta and Pt edge EXAFS results show that the temperature-dependent increase in structural disorder is greater around the Ta atoms in the CoCrTa system than it is around the Pt atoms in the CoCrPt system. © 1996 American Institute of Physics. I. INTRODUCTION

Compositional inhomogeneities have long been thought to play an important role in determining the magnetic properties of Co-Cr based magnetic thin films. Previous studies of CoCr-based thin films deposited at elevated temperatures indicated the presence of fine, periodic compositional variations within grains.¹ The addition of Ta has been shown to decrease the size of the Co enriched regions within these films, demonstrating the importance of the addition of Ta. Similarly, the addition of Pt has been shown to increase these films' coercivities. Previous studies have also proposed that nonmagnetic or paramagnetic Cr enriched regions^{2,3} between the magnetic Co enriched regions aid in decoupling the magnetic domains within these films thus leading to higher storage density and lower noise media.

The films investigated in this study were sputter deposited on glass substrates at temperatures (T_s) of room temperature and 260 °C. The nominal composition of the films studied were $\text{Co}_{86}\text{Cr}_{12}\text{Ta}_2$, and $\text{Co}_{86}\text{Cr}_{12}\text{Pt}_2$. The thickness of the films was 300 Å. All films were capped with a 50 Å layer of Al to prevent any oxidation effects, and had a 1000-Å-Cr underlayer.

The average local structure around the Co, Ta, and Pt atoms in these films was investigated by using polarization-dependent extended x-ray absorption fine structure (PD-EXAFS), a local structural probe having both elemental and directional sensitivity. Analysis of this data shows a greater amount of structural disorder around the Ta and Pt atoms with increasing substrate deposition temperature. A further comparison between the Ta and Pt edge PD-EXAFS results shows that the temperature-dependent increase in structural disorder is greater around the Ta atoms in the CoCrTa system

than it is around the Pt atoms in the CoCrPt system. Chemical segregation of Co-enriched regions within the films was confirmed also via PD-EXAFS at the Co absorption edge.

Magnetic circular dichroism (MCD) measurements were also made on these samples. MCD is an element-specific magnetic spectroscopic tool in which the difference in the absorption of left- and right-circularly polarized photons are measured at the absorption edges of the constituent elements. This difference in absorption cross sections, appropriately normalized, is a measure of the average magnetic moment of an atomic species at a given atomic site.^{4,5} Results from this study show the existence of a small average net magnetic moment associated with the Cr atoms that is opposite in direction relative to the average net magnetic moment of the Co atoms. MCD therefore enables measurement of direction and magnitude of the average magnetic moment for each constituent atomic species within a sample. Thus, it is a very good technique to use to determine if there is a magnetic moment associated with the Cr atoms within these films.

II. DATA COLLECTION AND ANALYSIS

PD-EXAFS and MCD measurements were performed on four films deposited on glass with nominal compositions $\text{Co}_{86}\text{Cr}_{12}\text{Ta}_2$, and $\text{Co}_{86}\text{Cr}_{12}\text{Pt}_2$ and T_s equal to room temperature and 260 °C.

X-ray absorption spectra were collected on the Naval Research Laboratory's materials analysis beam line, X23B, and the National Institute of Standards and Technology XAFS beamline X23A2, at the National Synchrotron Light Source (Brookhaven National Laboratory, Upton, NY). The fine structure appearing above the Co K edge (7709 eV), the Ta LIII-edge (9881 eV) and the Pt LII edge (13273 eV) were

FIG. 1. Fourier transform of Ta EXAFS data on $\text{Co}_{86}\text{Cr}_{12}\text{Ta}_2$ films grown at substrate deposition temperatures of room temperature (solid line) and 260 °C (dotted line).

collected in electron yield mode⁶ using normal and glancing angle (10° with respect to the film plane) incident radiation. Because the EXAFS signal originates with a \cos^2 angular dependence with respect to the electric-field vector of the incident radiation and the bond between the absorbing and backscattering atom, these orientations allow preferential sampling of the in-plane and out-of-plane structure, respectively. The EXAFS data were subjected to standard analysis procedures,⁷ leading to the Fourier transformation of the data to radial coordinates. To obtain quantitative measurement of the average near neighbor environment around the Co atoms, Fourier transformed data of the first Fourier peak from the Co *K*-edge PD-EXAFS data were back-Fourier transformed to wave vector space and fitted using parameterized theoretical EXAFS spectra. The theoretical EXAFS spectra were generated using the FEFF codes developed by Rehr and co-workers.⁸ This analysis allows the calculation of the average coordination number, radial distance, and Debye-Waller factors of atomic shells around each atomic species in both the parallel and perpendicular directions relative to the film surface.

MCD measurements were performed on these samples at beamline U4B and X13 at the National Synchrotron Light Source (Brookhaven National Laboratory, Upton, NY). MCD enables measurement of direction and magnitude of the average magnetic moment for each constituent atomic species within a sample. Thus, it is a very good technique to use to determine if there is a magnetic moment associated with the Cr atoms within these films. Measurements of the CoCrTa and CoCrPt films were made in the plane of the films while alternating the direction of the applied magnetic

FIG. 2. Fourier transform of Pt EXAFS data on $\text{Co}_{86}\text{Cr}_{12}\text{Pt}_2$ films grown at substrate deposition temperatures of room temperature (solid line) and 260 °C (dotted line).

field (10 kOe) between parallel and antiparallel orientations at each energy throughout the scan. The thickness of the glass substrate prohibited absorption measurements by transmission, therefore absorption was determined from the x-ray fluorescence signal⁹ as a function of incident energy and applied magnetic field. Since this study is only qualitatively addressing the existence of a magnetic moment associated with Cr, no fluorescence amplitude correction¹⁰ was included in the analysis.

III. RESULTS AND DISCUSSION

For all films, qualitative analysis of the Fourier Transformed PD-EXAFS data from the Co *K* edge show that the Co atoms are incorporated into the films in a close-packed structure.^{11,12} Results from a quantitative analysis of the filtered first shell data from the Co *K*-edge PD-EXAFS data indicate at least 95% of all the atoms surrounding the Co absorbing atoms are Co atoms. This is significantly larger than the 86% value expected had a solid solution of $\text{Co}_{86}\text{Cr}_{12}\text{Ta}_2$ or $\text{Co}_{86}\text{Cr}_{12}\text{Pt}_2$ had been formed. This illustrates the presence of Co-enriched regions within the films, and thus indirectly illustrates the presence of Cr-enriched regions.

Figures 1 and 2 are plots of the Fourier transformed Ta and Pt EXAFS data for T_s of room temperature (solid line) and 260 °C (dotted line). The general characteristic shapes of these data suggests that, for both substrate deposition temperatures, both the Ta and Pt atoms are incorporated within the films' close-packed structure with a large amount of local structural disorder. Furthermore, the local environment of the Ta and Pt atoms is not bcc or fcc clusters as one might expect if the Ta or Pt atoms had phase separated. Further analysis of the first Fourier transform peaks for the Ta and Pt data shows that for an increasing T_s , the average total number of atoms surrounding Ta and Pt decreases while the EXAFS Debye-Waller term increases. (An increase in the EXAFS Debye-Waller term corresponds to a broader distribution of radial distances about their average distance.) This temperature-dependent trend however, is not seen around the Co atoms in the CoCrTa or CoCrPt films. These two trends are consistent with vacancies preferentially segregating to the Ta or Pt atoms thereby decreasing the diffusion of the Co or Cr atoms, and thereby refining the length scale of the Co-enriched regions. A further comparison between the Ta and Pt edge PD-EXAFS results shows that the temperature-dependent increase in structural disorder is greater around the Ta atoms in the CoCrTa system than it is around the Pt atoms in the CoCrPt system.

Figures 3 and 4 are the MCD spectra for the Co and Cr atoms in a 2000-Å-thick $\text{Co}_{86}\text{Cr}_{12}\text{Ta}_2$ film with T_s at room temperature. MCD measurements were made on this sample instead of the 300 Å film because it did not have a 1000-Å-Cr underlayer which would contaminated the Cr MCD signal. These figures represent the difference in absorption of circularly polarized photons parallel and anti-parallel to an external magnetic field (10 kOe) applied in the plane of the films. The amplitude of these signals are normalized to the relative numbers of Co and Cr atoms in the film. The figure depicting the Co MCD spectra (Fig. 3) shows a negative

FIG. 3. MCD spectrum of the Co LIII and LII edges on the $\text{Co}_{86}\text{Cr}_{12}\text{Ta}_2$ film grown at room temperature.

FIG. 4. MCD spectrum of the Cr LIII and LII edges on the $\text{Co}_{86}\text{Cr}_{12}\text{Ta}_2$ film grown at room temperature.

difference signal at the LIII edge step and a positive difference signal at the LII edge step. Conversely, the figure depicting the Cr MCD spectra (Fig. 4) shows a positive signal at the LIII edge step and a negative signal at the LII edge step. The ratio of the magnitudes of the MCD effect for the Co and Cr atoms is approximately 20:1. A similar ratio exists for the 2000-Å-CoCrTa film grown with a 260 C T_s . This ratio does not exhibit any substrate deposition temperature dependence. In all cases, the absolute magnitude of this effect has not been corrected for self-absorption effects. However, although self-absorption effects may cause the amplitude of the MCD effect to change, the existence of the effect and its direction will not change. Therefore, this demonstrates that

- (1) there is a small net magnetic moment associated with the Cr atoms in the CoCrTa system,
- (2) the moment associated with the Cr atoms is anti aligned relative to the Co atoms, and
- (3) the ratio of the net Cr/Co magnetic moments is not temperature dependent.

IV. SUMMARY

In summary, we have used PD-EXAFS to verify that the local environments about the Co, Ta, and Pt atoms in $\text{Co}_{86}\text{Cr}_{12}\text{Ta}_2$, and $\text{Co}_{86}\text{Cr}_{12}\text{Pt}_2$ thin films are a close-packed structure. Results from analysis of the Co atoms' average first shell environments show Co-Co coordination numbers greater than that expected in a totally random case. This illustrates chemical segregation, within these films, into Co-enriched regions. Inspection of the Fourier transformed Ta edge and Pt edge PD-EXAFS data shows a change in the average local structure surrounding the Pt and Ta atoms in that there is a greater amount of structural disorder around these atoms with increasing substrate deposition temperature. A further comparison shows that the temperature-dependent increase in structural disorder is greater around the Ta atoms in the CoCrTa system than it is around the Pt atoms in the CoCrPt system. Results from the MCD measurements of

these films at the Co and Cr LIII and LII edges show that the average net magnetic moment of the Cr atoms is opposite in direction and five percent in amplitude relative to the Co moments. The amplitude and direction of the net magnetic moment of Cr exhibits no dependence on substrate deposition temperature.

Microstructure and magnetic properties of CoCrPt/Cr films on ultrasmooth NiP/AlMg substrates

Li Tang, David E. Laughlin, and David N. Lambeth
Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

Mary F. Doerner
IBM Storage Systems Division, 5600 Cottle Road, San Jose, California 95193

Investigation of the correlation between the microstructure and magnetic properties of $\text{Co}_{68}\text{Cr}_{20}\text{Pt}_{12}/\text{Cr}$ thin films which were sputter deposited under different conditions onto 95 mm ultrasmooth NiP/AlMg disk substrates ($R_a \sim 2 \text{ \AA}$) has been carried out. Grain morphology characteristics of the films and disk surface roughness were studied by transmission electron microscopy (TEM) and by atomic force microscopy. Tilted-specimen electron diffraction patterns were used to determine the crystallographic texture of the films. The low coercivity of the disks deposited at 100°C preheated substrates is attributed to the randomly oriented grains of the CoCrPt/Cr layers. Enhancement of the coercivity of the disks deposited on 220°C preheated substrates is thought to be mainly due to the $(11\bar{2}0)\text{CoCrPt}/(002)\text{Cr}$ crystallographic texture and uniformly distributed grains which are equiaxed in shape. The strength of the $(11\bar{2}0)\text{CoCrPt}/(002)\text{Cr}$ texture can be modified by the Ar gas pressure during the deposition of the Cr underlayer. © 1996 American Institute of Physics. [S0021-8979(96)09808-1]

For magnetic recording thin film media, structural characteristics such as grain size, shape, and separation, as well as composition inhomogeneity are believed to be closely related to the media magnetic and recording properties.^{1,2} Another important feature is the crystallographic texture of the films. This is difficult to measure by x-ray diffraction techniques for Co-alloy/Cr thin films deposited on NiP/AlMg substrates since the substrates are much thicker than the Co-alloy/Cr layers and usually contribute a strong background signal to the x-ray diffraction spectra of Co-alloy/Cr/NiP/AlMg disks.^{3,4} On the other hand, tilted electron diffraction patterns of both the Cr underlayer and Co-alloy film can be obtained separately from the same transmission electron microscopy (TEM) specimen in which thin areas of both the layers exist and the NiP/AlMg substrates are removed.⁵ From these diffraction patterns the texture axis and the distribution angle about the axis of the layers can be determined. Furthermore, information of grain morphology of the films including grain size, shape, and separation can also be obtained from TEM images. In this article, we present results of TEM and atomic force microscopy (AFM) studies of the microstructures of $\text{Co}_{68}\text{Cr}_{20}\text{Pt}_{12}/\text{Cr}$ films sputter deposited under different conditions onto ultrasmooth NiP/AlMg substrates. Correlation between the microstructure and magnetic properties of the films is also discussed.

$\text{Co}_{68}\text{Cr}_{20}\text{Pt}_{12}$ (220 \AA)/Cr (750 \AA) films were dc-magnetron sputter deposited onto 95 mm ultrasmooth NiP/AlMg disk substrates ($R_a \sim 2 \text{ \AA}$) at varying substrate tem-

peratures and Ar gas pressures (Table I). In-plane magnetic properties of the disks were measured using a vibrating sample magnetometer (VSM). Microstructural studies of the CoCrPt/Cr films were carried out using a Philips 420T transmission electron microscope. Specimen-tilted electron diffraction patterns were used to determine the crystallographic texture of the magnetic and underlayer films. This method has been described in detail elsewhere.^{5,6} Surface roughness of the disks was measured using an atomic force microscope.

In-plane magnetic properties of the CoCrPt/Cr/NiP/AlMg disks prepared under different conditions are listed in Table I. It can be noted that when the Ar gas pressure during the sputtering of Cr (15 mTorr) and of CoCrPt (5 mTorr) films is kept the same, raising the substrate temperature from 100°C (sample no. 1) to 220°C (sample no. 2) increases the coercivity of the CoCrPt film significantly. Reducing the Ar gas pressure from 15 to 5 mTorr during the deposition of the Cr underlayer on 220°C heated substrates, however, reduces the coercivity (sample no. 3) of the magnetic layer.

The bright field TEM images of the Cr underlayer and CoCrPt film at 0° tilt for sample no. 1 are shown in Figs. 1(a) and 2(a), respectively. The Cr grains in Fig. 1(a) (grains in dark contrast in this figure are residual CoCrPt grains which have not been totally removed) are well separated and elongated with a length to width ($\sim 100 \text{ \AA}$) ratio of 4:1. The CoCrPt grains in Fig. 2(a) are not obviously elongated in shape as are the grains of its Cr underlayer, and furthermore the grain size seems to have a wide distribution. Grain separation

TABLE I. Processing parameters and magnetic properties of CoCrPt/Cr thin films.

Sample no.	Substrate temperature ($^\circ\text{C}$)	Ar pressure CoCrPt/Cr (mTorr)	H_c (Oe)	$M_r T$ (memu/cm ²)	S^*
1	100	5/15	1360	0.68	0.91
2	220	5/15	2400	0.75	0.84
3	220	5/5	2000	0.75	0.91

FIG. 1. (a) Bright field TEM image at 0° tilt. Electron diffraction patterns at (b) 0° tilt and (c) 40° tilt of the Cr underlayer of sample no. 1.

ration is also noted between some of the grains. AFM measurement indicates that the surface of the disk after the media is deposited is much rougher ($R_a \sim 13 \text{ \AA}$) than the NiP/AlMg substrate. Electron diffraction patterns at 0° tilt and 40° tilt from the bcc Cr underlayer and from the hcp CoCrPt film of sample no. 1 are shown in Figs. 1(b) and 1(c) Figs. 2(b) and 2(c), respectively. No distinction can be made between the diffraction patterns at 0° and 40° tilt of the layers, indicating that grains in the Cr underlayer and CoCrPt film are randomly oriented three dimensionally. This may contribute to the low coercivity of this disk.

FIG. 2. (a) Bright field TEM image at 0° tilt. Electron diffraction patterns at (b) 0° tilt and (c) 40° tilt of the CoCrPt film of sample no. 1.

FIG. 3. (a) Bright field TEM image at 0° tilt. Electron diffraction patterns at (b) 0° tilt and (c) 50° tilt of the Cr underlayer of sample no. 2.

For sample no. 2, which was deposited at higher substrate temperature, the surface roughness (6 \AA) is much smaller than that of sample no. 1. The grains of the Cr underlayer [Fig. 3(a)] are no longer elongated but are equiaxed in shape and uniformly distributed with a grain size of about 230 \AA . This change of grain shape is believed to be due to the higher adatom mobility on the higher temperature substrate. Also, separation between some of the grains can be observed from Fig. 3(a). The Cr underlayer has a small amount of (002) texture, as can be seen from the change of the diffraction patterns when the specimen is tilted from 0° position [Fig. 3(b)] to 50° [Fig. 3(c), OT is the tilt axis

FIG. 4. (a) Bright field TEM image at 0° tilt. Electron diffraction patterns at (b) 0° tilt and (c) 50° tilt of the CoCrPt film of sample no. 2.

FIG. 5. (a) Bright field TEM image at 0° tilt. Electron diffraction patterns at (b) 0° tilt, (c) 30° tilt, and (d) 42° tilt of the Cr underlayer of sample no. 3.

direction]. Correspondingly, grains of the CoCrPt film are also equiaxed in shape but without separation [Fig. 4(a)] and there is a tendency for (11 $\bar{2}$ 0) texture, as can be seen from the diffraction patterns at 0° [Fig. 4(b)] and 50° tilt [Fig. 4(c)]. It is well known that (11 $\bar{2}$ 0) textured CoCrPt bicrystals with the *c* axis 90° relative to each other grow on (002) textured Cr grains.⁷ Micromagnetic modeling studies show that exchange coupling between the bicrystals reduces the coercivity of the magnetic layer significantly.⁸ Since the CoCrPt(11 $\bar{2}$ 0)/Cr(002) texture is weak in this disk, the above mentioned effect is also weak which allows a high in-plane anisotropy and therefore high in-plane coercivity and small *S**. It seems that equiaxed grain shape is also important for the coercivity enhancement of this disk.

The grain shape of the Cr underlayer [Fig. 5(a)] and CoCrPt film [Fig. 6(a)] for sample no. 3 is similar to that of sample no. 2. But the grain size is a slightly smaller (~200 Å) and the disk surface roughness is further reduced to 3.5 Å as measured by AFM. No grain separation is observed in either of the layers. The (002) Cr and (11 $\bar{2}$ 0) CoCrPt textures of this disk are much stronger than that observed in sample no. 2. This can be seen from the diffraction patterns of the Cr underlayer at 0°, 30°, and 42° tilt [Figs. 5(b)–5(d)] and the CoCrPt film at 0°, 36°, and 56° tilt [Figs. 6(b)–6(d)]. The distribution angles of the Cr [002] and CoCrPt [11 $\bar{2}$ 0] texture axis are determined to be 10° and 6°, respectively.⁵ The coercivity (2000 Oe) of this disk, however, is lower than that of sample no. 2. This is believed to be due to the lower effective anisotropy of the strongly exchange coupled CoCrPt bicrys-

FIG. 6. (a) Bright field TEM image at 0° tilt. Electron diffraction patterns at (b) 0° tilt, (c) 36° tilt, and (d) 56° tilt of the CoCrPt film of sample no. 3.

tals arising from the strong CoCrPt (11 $\bar{2}$ 0)/Cr (002) texture.⁸ The slightly smaller grain size may also play a role here.

In summary, the grains of both the Cr underlayer and CoCrPt films deposited at 100 °C preheated substrates are randomly oriented and result in the low in-plane coercivity. For films deposited on substrates which were preheated to 220 °C, the enhancement of in-plane coercivity is believed to be mainly due to the (11 $\bar{2}$ 0) CoCrPt/(002)Cr texture. In order to achieve the highest in-plane coercivity the strength of the (11 $\bar{2}$ 0)CoCrPt/(002)Cr texture seems to be of critical importance. The surface roughness (3.5–6 Å) of the disks deposited on higher temperature substrates is much lower than that (13 Å) of the disks deposited on low temperature substrates. The correlation between the surface roughness and the magnetic properties, however, needs further study.

Effects of Ti addition to a Cr underlayer on the magnetic and crystallographic properties of Co–Cr–Pt media were investigated. C/Co–Cr₂₀–Pt (Pt: 8 and 12 at. %)/Cr–Ti (Ti: 0–30 at. %) films were deposited on textured Ni–P/Al–Mg substrates by dc magnetron sputtering. In-plane H_c and S^* increased as Ti was added to the Cr underlayer. The media noise at 167 kFCI decreased with an increase of the Ti content from 0 to 20 at. %. The normalized media noise of Co₇₂Cr₂₀Pt₈/Cr₇₅Ti₂₅ media was 20% lower than that of Co₆₈Cr₂₀Pt₁₂/Cr₉₀Ti₁₀ media where their coercivity and S^* were almost the same. Further increase of the Ti caused the increase of the media noise. Transmission electron microscopy studies showed that average grain size of Cr–Ti films decreased from 30 to 20 nm with the increase of the Ti content from 0 to 20 at. %. The activation volume of Co₆₈Cr₂₀Pt₁₂ films measured from the time dependences of remanence coercivity decreased by 30% as the Ti content increased from 0 to 20 at. %. The reduction of media noise is probably due to the decrease of the magnetic switching volume which is caused by the reduction of the grain size of Cr–Ti underlayers. © 1996 American Institute of Physics. [S0021-8979(96)09908-8]

I. INTRODUCTION

Magnetic recording media are required to have high coercivity, high S^* , and low media noise to achieve higher areal density of rigid disk drives. Co–Cr–Pt/Cr thin film media have been developed as the candidate for gigabit density recording.^{1,2} Coercivity of the Co–Cr–Pt films increased as Ti was added to Cr underlayers.³ A possible mechanism for the coercivity increase is the decrease of lattice mismatch between the underlayers and the Co–Cr–Pt films.³

It is also suggested that the magnitude of the intergranular exchange interactions in the Co–Cr–Pt films is large for the film with high Pt content.⁴ The large exchange interaction causes the increase of the media noise. The physical separation of crystal grains or Cr segregation in the Co–Cr–Pt films is effective in reducing the media noise.⁵ This article reports the reduction of media noise of the Co–Cr–Pt media by the addition of Ti to the Cr underlayers. The mechanism of the noise reduction is discussed using the results of magnetic viscosity measurements and microstructure analyses.

II. EXPERIMENT

A Cr–Ti alloy underlayer (30-nm-thick), a Co–Cr–Pt alloy magnetic layer (23-nm-thick), and a C protective layer (10-nm-thick) were successively deposited on textured Ni–P-plated Al–Mg-alloy substrates ($R_a=3$ nm) using a dc magnetron sputtering system. The substrate temperature was 270 °C and the Ar pressure was 5 mTorr. The Ti content of the Cr–Ti underlayers was changed from 0 to 30 at. % by changing the composition of the Cr–Ti-alloy targets. The compositions of magnetic films studied were Co₇₂Cr₂₀Pt₈ and Co₆₈Cr₂₀Pt₁₂. The remanence thickness product ($B_r t_{\text{mag}}$) was adjusted by 100 G μm for both magnetic film compositions. Magnetic properties were measured by a vibrating sample magnetometer with a maximum applied field of 10 kOe. The product of activation volume and saturation mag-

netization (vI_s) was evaluated by measuring a time dependence of remanence coercivity (H_r).⁶ vI_s is given by the following equations:

$$vI_s = kT/H_f, \quad (1)$$

$$H_r(t) = -H_f \ln t + \text{const}, \quad (2)$$

FIG. 1. Dependence of magnetic properties of Co–Cr–Pt/Cr–Ti media on Ti content.

FIG. 2. Plan-view TEM images of the magnetic layer and underlayer of $\text{Co}_{68}\text{Cr}_{20}\text{Pt}_{12}/\text{Cr}$ and $\text{Co}_{68}\text{Cr}_{20}\text{Pt}_{12}/\text{Cr}_{80}\text{Ti}_{20}$.

where I_s is the saturation magnetization in the activation volume (v), k is Boltzmann's constant, and H_f is the fluctuation field. The crystallographic texture of the films was analyzed by x-ray diffractometry with $\text{Cu } K\alpha$ radiation. Transmission electron microscopy (TEM) was used to measure the average grain sizes of the Co–Cr–Pt magnetic layers and the Cr–Ti underlayers. Media noises were measured using a magnetoresistive (MR) head with a read track width of $2.6 \mu\text{m}$ at a magnetic spacing of 70 nm. We defined a normalized media noise using the media noise (N_d) that was integrated in a noise spectrum, isolated output ($V_{\text{p-p}}$ where the subscript means peak-to-peak), and the read track width (T_w) as the following equation:

$$\text{Normalized } N_d = N_d \sqrt{T_w} / V_{\text{p-p}}. \quad (3)$$

III. RESULTS AND DISCUSSION

A. Magnetic and crystallographic properties

Figure 1 shows the H_c and S^* as a function of Ti content. H_c increased as Ti was added, and showed a maximum value at 25 at. % Ti. S^* monotonously increased with the addition of Ti. The crystallographic texture of Co–Cr–Pt(11.0)/Cr–Ti(100) was observed in all specimens. The enhancement of H_c and S^* is probably due to the lattice matching between Co–Cr–Pt and Cr–Ti films by expanding the Cr lattice with the addition of Ti.³

Figure 2 shows the plan-view TEM images of the magnetic layers and the underlayers of $\text{Co}_{68}\text{Cr}_{20}\text{Pt}_{12}/\text{Cr}$ and $\text{Co}_{68}\text{Cr}_{20}\text{Pt}_{12}/\text{Cr}_{80}\text{Ti}_{20}$ films. The grain size of Cr–Ti film is significantly smaller than that of the pure Cr. Figure 3 shows the average grain size of Cr–Ti films. The grain sizes decreased from 30 to 20 nm with the increase of the Ti content from 0 to 20 at. %. The decrease of grain size seems to correlate to the nucleation density of the Cr–Ti films. Further study is necessary to learn more about the change of grain sizes.

FIG. 3. Dependence of the average Cr–Ti grain size on Ti content.

On the other hand, the change of Co–Cr–Pt grain size is not accurately calculated because of the relatively diffused grain boundaries as shown in Fig. 2.

B. Activation volume

The activation volume (v) is recognized as the size of the magnetic reversal unit of magnetic films.^{7–9} Figure 4 shows the dependence of vI_s on the Ti content for $\text{Co}_{72}\text{Cr}_{20}\text{Pt}_8/\text{Cr}$ –Ti and $\text{Co}_{68}\text{Cr}_{20}\text{Pt}_{12}/\text{Cr}$ –Ti films. vI_s decreased by about 30% with an increase of the Ti content from 0 to 20 at. %. Assuming that the I_s is the average value for the total quantity of the Co–Cr–Pt film, the reduction of vI_s corresponds to the decrease of the activation volume (v) from 3.8×10^{-18} to $2.3 \times 10^{-18} \text{ cm}^3$ in the case of $\text{Co}_{68}\text{Cr}_{20}\text{Pt}_{12}/\text{Cr}$ –Ti films. If the magnetic reversal unit is assumed as columnar shape with a height of magnetic film thickness, the diameter of the column is estimated as 15 and 11 nm with the Ti content of 0 and 20 at. %. The calculated

FIG. 4. Dependence of vI_s ($=kT/H_f$) of Co–Cr–Pt/Cr–Ti media on Ti content.

FIG. 5. Normalized media noise of Co-Cr-Pt/Cr-Ti media on Ti content for (a) recording density of 167 kFCI, and (b) dc erased state.

diameter is similar to the observed value in TEM image as shown in Fig. 2. The decrease of magnetic switching volume is probably caused by the reduction of grain size of Cr-Ti underlayer. This is because the reduction ratio of vI_s is almost equal to the decrease of the Cr-Ti grain size with the addition of Ti as shown in Fig. 3.

On the other hand, vI_s increased at the Ti content larger than 20 at. %. The reason for the increase of vI_s at high Ti content is discussed in the following section.

C. Media noise characteristics

Figure 5 shows the normalized media noise (N_d) of Co-Cr-Pt/Cr-Ti media as the function of the Ti content. At a recording density of 167 kilo flux change per inch (kFCI) [Fig. 5(a)] the normalized N_d decreased with an increase of the Ti content from 0 to 20 at. %. The normalized N_d of Co₇₂Cr₂₀Pt₈/Cr₇₅Ti₂₅ media was about 20% lower than that of Co₆₈Cr₂₀Pt₁₂/Cr₉₀Ti₁₀ media, where coercivity and S^* of the media are almost the same. As the change of activation volume with Pt content was small compared to the change by the Ti content, it is considered that the reduction of normal-

ized N_d is due to the decrease of magnetic switching volume which is caused by the reduction of the grain size of Cr-Ti underlayers.

It has been proposed that the media noise is reduced by the decreasing exchange interaction between the crystal grains, which leads to a decrease of S^* .⁵ However, the decrease of S^* causes the decrease of the read output. Accordingly, the addition of Ti to Cr underlayer is advantageous since the noise is reduced without the decrease of S^* .

The normalized N_d , especially the dc erase noise, increases with the increase of the Ti content from 25 to 30 at. %. No significant change was observed in the crystallographic texture of Co-Cr-Pt(11.0)/Cr-Ti(100) films at this composition. From the structural analyses it seemed that the increase of N_d was caused by the increase and a wider distribution of grain size of Cr-Ti films at the high Ti content.

IV. CONCLUSIONS

Effects of Ti addition to a Cr underlayer on the magnetic and crystallographic properties were investigated. An increase of the Ti content resulted in an increase of H_c and S^* and a decrease of media noise. The grain sizes of Cr-Ti films decreased from 30 to 20 nm with the increase of the Ti content from 0 to 20 at. %. The reduction of media noise is assumed to be due to the decrease of magnetic switching volume which is caused by the reduction of the grain size of the Cr-Ti underlayer. Ti addition to Cr underlayers is advantageous to improve the recording properties since the media noise is remarkably reduced without a decrease of S^* .

Magnetic and crystallographic properties of CoCrPt thin films formed on Cr-Ti single crystalline underlayers

N. Inaba, A. Nakamura, T. Yamamoto, Y. Hosoe, and M. Futamoto
Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo 185, Japan

By using an epitaxial growth technique, $\text{Co}_{73}\text{Cr}_{15}\text{Pt}_{12}(11\bar{2}0)$ bi-crystalline thin films formed on $\text{Cr-Ti}_x(001)[x=0-15 \text{ at. \%}]$ single crystalline underlayers were prepared to investigate the relationship between the magnetic properties and the lattice distortion in the magnetic layer. X-ray diffraction measurement shows that the best lattice matching between the c axis of the CoCrPt and the $[110]$ direction of the Cr-Ti underlayer is realized and the CoCrPt layer shows an ideal symmetrical hcp. structure when the Ti concentration is 10 at. %, where the maximum magneto-crystalline anisotropy energy and coercivity values are observed. Distortion in the hcp. CoCrPt magnetic crystal grains decreases the uniaxial magneto-crystalline anisotropy energy, thus lowering the attainable medium coercivity. © 1996 American Institute of Physics.

I. INTRODUCTION

Magnetic properties of longitudinal magnetic recording media depend on the crystalline orientation relationship between the magnetic layer and the underlayer.^{1,2} The crystal lattice distortion is caused by the lattice misfit between the magnetic layer and the underlayer. However, the inter-relationship among these properties has not yet been precisely made clear for practical media, since they consist of very small polycrystalline grains.

In our previous works,^{3,4} Co/Cr and CoCrPt/Cr bilayer thin films are epitaxially grown on $\text{MgO}(001)$ single crystal substrates with the crystallographic orientation relationship of $\text{MgO}(001)[100] \parallel \text{Cr}(001)[110] \parallel \text{Co}$ or $\text{CoCrPt}(11\bar{2}0)[0001]$. The Cr layer has a (001)-oriented single-crystalline structure, while the magnetic layer shows a bi-crystalline structure consisting of two different domains with their c axes lying in-plane and aligned perpendicular to each other. By using well defined specimens, the magnetocrystalline anisotropy of the magnetic layer as well as the lattice spacings of both the layers can be precisely determined.⁵

In the present research, by using the epitaxial growth technique, we prepared CoCrPt bi-crystalline thin films grown on Cr-Ti single crystalline underlayers while changing the Ti concentration in the underlayer to vary the lattice constant of the underlayer. The relationship between the fundamental magnetic and crystallographic properties for the CoCrPt/Cr-Ti bi-layer film system is investigated.

II. EXPERIMENTAL PROCEDURE

Thin films were deposited by using a dc magnetron sputtering system on $\text{MgO}(001)$ single crystal substrates kept at 300°C under an Ar pressure of 3 m Torr. A Cr-Ti underlayer (50 nm), $\text{Co}_{73}\text{Cr}_{15}\text{Pt}_{12}$ magnetic layer (25 nm) and a carbon overcoat layer (10 nm) were sequentially formed on MgO substrates. Ti concentration in the Cr-Ti underlayer was changed from 0 to 15 at. %.

The crystal lattice parameters were determined by x-ray diffraction analysis. Plan-view microstructures of the magnetic layer were observed using a transmission electron mi-

croscope (TEM). Magnetic torque curves and magnetization curves were measured by using a torque magnetometer and a vibrating sample magnetometer, respectively.

III. RESULTS AND DISCUSSIONS

A. Lattice structure of CoCrPt thin films

All the specimens showed only the Cr-Ti(002), the CoCrPt(11 $\bar{2}0$) and the MgO(002) sharp peaks in the θ - 2θ scan x-ray diffraction, which indicated epitaxial growth of these films. Figure 1 shows the variation of lattice spacing and the full width at half maximum ($\Delta\theta_{50}$) of an x-ray reflection rocking curve measured for the Cr-Ti(002) and the CoCrPt(11 $\bar{2}0$) layers when Ti concentration in the Cr-Ti underlayers is changed. The lattice spacing of Cr-Ti(002) increases linearly by increasing the Ti concentration. The $\Delta\theta_{50}$ of the Cr-Ti layer is almost constant at 0.4° - 0.5° . On the contrary, by increasing the Ti concentration, the lattice spacing of CoCrPt(11 $\bar{2}0$) decreases taking the minimum value of 1.286 Å at 10 at. % Ti. The $\Delta\theta_{50}$ of CoCrPt(11 $\bar{2}0$) decreases monotonically down to 0.9° by increasing the Ti concentration to 15 at. %. This result suggests that the crystallographic orientation of the CoCrPt layer is more aligned with increasing the lattice constant of the underlayer.

FIG. 1. Lattice spacings and full width at half maximum ($\Delta\theta_{50}$) of x-ray reflection rocking curves for Cr-Ti(002) and CoCrPt(11 $\bar{2}0$) when Ti concentration in the Cr-Ti underlayer is changed.

FIG. 2. Variations of lattice spacing for Cr-Ti(112) and lattice parameters, a and a' , when Ti concentration is changed.

We measured the lattice parameters of the films that were parallel and not parallel to the substrate plane by θ - 2θ scan x-ray diffraction measurements for the samples set with offset angles in order to determine accurately the crystal structures of the CoCrPt/CrTi bi-layer films. The lattice parameters of the Cr-Ti underlayer parallel and perpendicular to the film plane, a and a' , are estimated by the lattice spacings of the Cr-Ti(002) and (112) planes shown in Figs. 1 and 2. The [100] and [010] axes of the Cr-Ti crystal are equivalent. Both a and a' parameters increase by increasing the Ti concentration. However, the a' parameter is about 0.5% smaller than a parameter, which shows that the bcc. lattice of Cr-Ti crystals formed on the MgO(001) substrates is deformed about 0.5% from an ideal symmetrical bcc. structure.

The lattice parameters of the CoCrPt hexagonal closed-packed structure, a , a' , and c , were estimated by the lattice spacings of CoCrPt(11 $\bar{2}$ 0), (20 $\bar{2}$ 0), and (11 $\bar{2}$ 2) planes, as shown in Fig. 3. The dotted line in Fig. 3 is the variation of the two times of the Cr-Ti(110) lattice spacing, which coincide with the lattice spacing of CoCrPt(0001), or the c parameter, under an epitaxial growth condition. The a parameter remains almost unchanged regardless of the Ti concentration in the underlayer. On the other hand, the a' and c parameters increase by increasing the Ti concentration in the underlayer and shows the maximum value at the Ti con-

FIG. 3. Variations of lattice spacing measured for CoCrPt(20 $\bar{2}$ 0), CoCrPt(11 $\bar{2}$ 2), and lattice parameters, a , a' , and c when Ti concentration in the underlayer is changed.

FIG. 4. Plan-view microstructure of epitaxially grown CoCrPt, (a) selected-area electron diffraction pattern, (b) indexed electron diffraction pattern, (c) and (d) show the dark field images for the same area which are observed by using the diffraction spots a and b indicated in (a), respectively.

centration of 10 at. %, where the lattice mismatch between the c axis of the CoCrPt and the [110] direction of the Cr-Ti underlayer is minimized. The ratio of a'/a also increases by increasing the Ti concentration and approaches to 1.0 for the same underlayer composition. Since the CoCrPt layer is epitaxially grown on the underlayer, the crystal lattice distortion is introduced to the CoCrPt magnetic crystals by increasing of the lattice misfit between the magnetic layer and the underlayer.

Plan-view microstructure of the CoCrPt layer was observed by using a TEM. Figures 4(a) and 4(b) show the selected-area electron diffraction pattern and the diffraction index, respectively. The result indicates the CoCrPt layer has (11 $\bar{2}$ 0) orientation and consists of two different types of domains with the c axes perpendicular to each other. Figures 4(c) and 4(d) show the dark field TEM images observed from a same area of the CoCrPt layer by using the diffraction spots of a and b indicated in Fig. 4(a). The magnetic grain size is about 20 nm in diameter. Several grains that have a same crystal orientation tend to form a continuous larger size grain.

B. Magnetocrystalline anisotropy of CoCrPt

The magneto-crystalline anisotropy of the CoCrPt thin films was determined by magnetic torque measurements. The magnetic field, H_{ex} , is applied in the (001) plane of the MgO substrates, or the CoCrPt(11 $\bar{2}$ 0) plane. Since the CoCrPt layer shows bi-crystalline structure consisting of two types of domains with the c axes perpendicular to each other, the magnetic anisotropy energy per unit volume, E_{in} , is given by the following equation:

$$E_{in} = K_{u1}/2 + K_{u2}(\sin^4 \theta_{in} + \cos^4 \theta_{in})/2. \quad (1)$$

Where K_{u1} and K_{u2} are the magneto-crystalline anisotropy constants, θ_{in} is an angle between the direction of magneti-

FIG. 5. Variations of K_{u1} , K_{u2} , and H_c measured for CoCrPt layer when Ti concentration in the underlayer is changed.

zation and the MgO[100] axis, and the two types of bi-crystalline domains have the same volume. The magnetic torque, L_{in} , is given by

$$L_{in} = -\partial E_{in} / \partial \theta_{in} = (K_{u2}/4) \sin 4\theta_{in}. \quad (2)$$

The direction of H_{ex} was varied out of the CoCrPt film plane around the MgO[010] axis. In this case, the magnetic anisotropy of the magnetic domains, whose c axes are parallel to the MgO[010] direction, can be ignored. The magnetic anisotropy energy per unit volume, E_{out} , and the magnetic torque, L_{out} , are given by

$$E_{out} = (K_{u1} \sin^2 \theta_{out} + K_{u2} \sin^4 \theta_{out})/2 + 2\pi M_s^2 \sin^2 \theta_{out}, \quad (3)$$

$$L_{out} = (K_{u1}/2 + K_{u2}/2 + 2\pi M_s^2) \sin 2\theta_{out} - (K_{u2}/4) \sin 4\theta_{out}, \quad (4)$$

where $2\pi M_s^2$ is the shape anisotropy energy, and θ_{out} is the angle between the direction of the magnetization and the MgO[100] axis. Therefore, K_{u1} and K_{u2} can be obtained by Fourier analysis of the torque curves.

The magnetic torque curves of the CoCrPt thin films measured in the MgO(001) plane had fourfold symmetry. The directions of the c axes in the CoCrPt bi-crystal films, which are parallel either to MgO[100] or [010] directions, are the effective magnetic hard axes. Since the components proportional to $\sin 2\theta_{in}$ in the curves are less than one tenth of that of $\sin 4\theta_{in}$, two types of bi-crystalline domains have the same volume. Figure 5 shows the variations of K_{u1} and K_{u2} of the CoCrPt thin films determined by using the above mentioned technique. By increasing the Ti concentration in the Cr-Ti underlayer, both K_{u1} and K_{u2} increase and show

the maximum values of 3.4×10^6 erg/cc (K_{u1}) and 1.8×10^6 erg/cc (K_{u2}) at the Ti concentration of 10 at. %, where the best lattice matching between the magnetic layer and underlayer is realized. The coercivity of the CoCrPt specimen, H_c , also shows the maximum value at the same underlayer composition. The variation of coercivity corresponds to that of the magneto-crystalline anisotropy energy. These results clearly indicate that the K_{u1} and the K_{u2} of the film show the maximum values when the crystallographic distortion of the CoCrPt magnetic crystals formed on the underlayer is minimized. Therefore, it is very important to realize a good lattice matching between the magnetic layer and the underlayer in order to increase the coercivity of longitudinal magnetic recording media.

IV. CONCLUSIONS

We investigated the relationship between the crystalline distortion and the magneto-crystalline anisotropy for the CoCrPt/Cr-Ti[Ti:0–15 at. %] bi-layer film system prepared by using the epitaxial growth technique. The lattice constant of the Cr-Ti underlayer increases from 2.88 to 2.94 Å by increasing the Ti concentration from 0 to 15 at. %. When the CoCrPt bi-crystalline thin film is formed on the Cr-10 at. % Ti underlayer, the best lattice matching between the c axis of the CoCrPt and the [110] direction of the Cr-Ti underlayer is realized and the CoCrPt layer shows an ideal symmetrical hcp. structure. This CoCrPt layer possesses the maximum values of K_u (3.4×10^6 erg/cc) and H_c (2.2 kOe). The distortion in the hcp. crystal structure decreases the uniaxial magneto-crystalline anisotropy energy of the CoCrPt material, thus lowering the attainable medium coercivity.

CoCrTa/Cr/Al and CoCrTa/Cr thin films were deposited on glass substrate at 280 °C using dc magnetron sputtering. The coercivity of CoCrTa/Cr films increased by introducing an Al underlayer. In 500 Å CoCrTa/Cr films, the coercivity increased with increasing Cr thickness and saturated above 700 Å Cr thickness ($H_c=1050$ Oe). On the other hand, in 500 Å CoCrTa/Cr/700 Å Al films, the coercivity increased sharply with increasing Cr thickness and showed a maximum value at 700 Å Cr thickness ($H_c=1380$ Oe). The coercivity squareness of the CoCrTa/Cr/Al and CoCrTa/Cr films was increased with increasing Cr thickness. The coercivity squareness of CoCrTa/Cr/Al films was lower than that of CoCrTa/Cr films. To study the origin of coercivity enhancement in CoCrTa/Cr films when deposited on an Al underlayer, microstructures of the two films were investigated using transmission electron microscopy (TEM). We controlled grain sizes of CoCrTa films by changing the thickness of the Cr layer. The grain size of CoCrTa films increased with increasing Cr thickness. The coercivity of CoCrTa/Cr/Al films showed a maximum value at a grain size of 430 Å. These results suggest that the transition from single domain to multidomain could occur at a grain size of ~ 400 Å. To understand the coercivity squareness changes by the introduction of an Al underlayer, the angular variation of coercivity was measured. The magnetization of CoCrTa/Cr films was reversed by domain wall motion. On the other hand, by the incorporation of an Al underlayer, the angular variation of coercivity deviated from the domain wall motion mode. Cross-sectional TEM studies of CoCrTa/Cr/Al films showed that Cr atoms in Cr layers diffused into an Al underlayer and Al atoms were detected in both Cr and CoCrTa layers, but magnetization of the magnetic layer was not decreased. The decrease in coercivity squareness of CoCrTa/Cr/Al films would be attributed to magnetic decoupling by segregation of Al atoms in grain boundaries of CoCrTa films. © 1996 American Institute of Physics. The magnetic properties of high density recording media have been shown to be very sensitive to the film microstructure. We have investigated the influences of different sputter gases (Ar, Xe, Kr) and different sputter pressures (3 to 24 mTorr) on the microstructures and magnetic properties of CoPtCr/Cr thin films. The magnetic properties of the films (coercive field, H_c , coercive squareness, S^* , and remanant moment, M_r) were determined using a vibrating sample magnetometer. The microstructures were examined by transmission electron microscopy and x-ray diffraction. For all three gases studied the microstructures and properties of the CoPtCr films were found to change with sputter pressure in similar manners. Films deposited at the lowest pressure consisted of well connected, equiaxed grains. With only a slight increase in pressure, the grains formed chains separated by small gaps. As the gas pressure increased further, the chains became better defined and the gaps between them widened. The coercive squareness and coercive field correlate with the film microstructures. S^* decreased with increasing sputter gas pressure, and H_c first increased and then decreased. For all three sputter gases, H_c reached a maximum around 12 mTorr. Likewise, S^* decreased quite slowly with increasing pressure up to 12 mTorr and then exhibited a sharp drop between 12 and 18 mTorr. From these results it appears that the sputter pressure, rather than the mass of the sputter gas, is most important for the microstructural development of the film. Likewise, the values of S^* were found to be independent of the sputter gas. However, in spite of the similar microstructures, films deposited with Ar had higher values of H_c than films deposited with Xe or Kr, for all sputter pressures examined. The role of the sputter gas mass will be discussed. © 1996 American Institute of Physics. [S0021-8979(96)46008-X]

Improvement of $\text{Co}_{71}\text{Cr}_{19}\text{Pt}_{10}/\text{Ti}_{90}\text{Cr}_{10}$ perpendicular recording media by independent optimization of film nucleation and growth processes

T. P. Nolan, Y. Hirayama, and M. Futamoto
Central Research Laboratory, Hitachi, Ltd., Kokubunji, Tokyo 185, Japan

$\text{CoCrPt}/\text{TiCr}$ perpendicular recording media having independently optimized nucleation and growth conditions have been prepared by changing the argon pressure during sputter deposition of each film. A low argon pressure CoCrPt nucleation layer produces strong c -axis perpendicular orientation that can be maintained during continued CoCrPt deposition at high argon pressure. The two-layer media combines increased particle separation from high pressure growth and strong orientation to produce higher signal to noise ratio than either high pressure or low pressure single layer CoCrPt media. TiCr underlayers, despite poor orientation and a noncolumnar structure, improve CoCrPt c -axis perpendicular orientation. Low argon pressure during TiCr deposition maximizes CoCrPt orientation. A TiCr bilayer having a low pressure nucleation layer followed by a high pressure growth layer improves performance of the subsequent CoCrPt layer. A TiCr bilayer having a high pressure growth layer followed by a thin low pressure template produces even greater recording performance enhancement. This media has $H_c = 2560$ Oe, $D_{50} = 90$ kfc and S_0/N_d at 240 kfc = 4.0. An identical CoCrPt layer deposited on the low pressure TiCr underlayer has $H_c = 1850$ Oe, $D_{50} = 80$ kfc and S_0/N_d at 240 kfc = 2.4. © 1996 American Institute of Physics. [S0021-8979(96)28008-6]

I. INTRODUCTION

The ultimate density limit of perpendicular recording may be higher than that of longitudinal recording.^{1,2} Perpendicular media combined with new technology for in contact recording systems using integrated circuit (IC) process fabricated giant magnetoresistance microflex-heads is promising.³

Hexagonal, sputtered CoCrPt alloys similar to those used in longitudinal recording have sufficient magnetocrystalline anisotropy to counteract the demagnetization and shape anisotropy of the perpendicular geometry, and microstructural features desirable for perpendicular magnetic recording.⁴ They naturally grow with the required c -axis vertical orientation on many materials.⁵⁻⁹

Seed layers are used to improve CoCrPt microstructural, crystallographic and magnetic properties.⁶⁻⁹ $\text{Ti}_{90}\text{Cr}_{10}$ underlayers have been demonstrated to improve CoCrPt microstructure and c -axis vertical orientation on SiO_2/Si substrates. Promising media having higher signal-to-noise ratio (SNR) at >200 kfc than comparable longitudinal media, at recording densities above 200 kfc, have already been demonstrated.⁶ However, optimization of the microstructure to further increase SNR and D_{50} is required.

This is difficult because microstructure varies with each deposition parameter of both the TiCr and CoCrPt layer depositions. Ideal deposition conditions for film nucleation and film growth also differ. Furthermore, optimal CoCrPt nucleation may require a template layer, giving the five separate growth steps shown schematically in Fig. 1.

This paper demonstrates a method for independently tailoring the microstructure of these five stages of magnetic recording media film growth. Argon pressure (P_{Ar}) is changed during deposition from one target, to change the adatom mobility during the different growth stages. Control of mobility by adjustment of argon pressure is chosen for its feasibility in production applications.

Small separated grain structures are produced with reduced loss of preferred orientation, giving rise to improved CoCrPt magnetic properties.

II. MEDIA PREPARATION AND ANALYSIS

100 nm $\text{Co}_{71}\text{Cr}_{19}\text{Pt}_{10}$ magnetic layers and 30 nm $\text{Ti}_{90}\text{Cr}_{10}$ underlayers were dc magnetron sputter deposited onto rf sputter cleaned, oxidized silicon wafers. Substrates were heated to 230 °C with base pressure maintained below 10^{-8} Torr. Samples are separated into two groups.

Group A samples have identical TiCr underlayers deposited with $P_{\text{Ar}} = 2$ mTorr. Sample A1 has $P_{\text{Ar}(\text{CoCrPt})} = 2$ mTorr. Sample A2 has $P_{\text{Ar}(\text{CoCrPt})} = 15$ mTorr. Sample A3 was prepared by depositing 10 nm of CoCrPt under conditions identical to A1, followed by 90 nm deposited under the conditions for A2.

Group B samples all have $P_{\text{Ar}(\text{CoCrPt})} = 2$ mTorr. Sample B1 has $P_{\text{Ar}(\text{TiCr})} = 2$ mTorr. Sample B2 has a 5 nm nucleation layer with $P_{\text{Ar}(\text{TiCr})} = 2$ mTorr followed by a 25 nm growth layer with $P_{\text{Ar}(\text{TiCr})} = 35$ mTorr. Samples were also deposited

FIG. 1. Model of microstructure development stages for deposition optimization.

TABLE I. Group A data.

Sample	CoCrPt θ_{50} (deg)	Particle size (nm)	$H_{c\perp}$ (Oe)	$H_{c\parallel}$ (Oe)
A1	2.2	43	1850	220
A2	4.8	74	1060	350
A3	3.7	39	1840	220

with 15 nm and 45 nm growth layers. Sample B3 has a 25 nm, $P_{\text{Ar(TiCr)}}=35$ mTorr growth layer followed by a 5 nm, $P_{\text{Ar(TiCr)}}=2$ mTorr template layer.

Preferred orientation strength was measured from x-ray rocking curves of the TiCr and CoCrPt {0002} peaks. Surface morphology was analyzed using a Hitachi S5000 FESEM with samples heated to 150 °C to reduce contamination. Hysteresis loops were measured perpendicular and parallel to the thin-film plane by vibrating-sample magnetometry (VSM).

Recording measurements employed a composite head having a permalloy inductive write head with track width, $T_w=10.3$ μm , and gap length, $G_l=0.6$ μm ; and a magnetoresistance (MR) read head with $T_w=3.4$ μm and $G_l=0.5$ μm . Write and read head flying heights were 65 nm and 60 nm respectively, head velocity was 4.0 m/s and the writing current was 35 mA. Low frequency output signal (S_0), recording density giving output voltage= $S_0/2$ (D_{50}), media noise at 240 kfc (N_d), and S_0/N_d were measured.

III. CoCrPt NUCLEATION AND GROWTH

Low P_{Ar} (A1) provides stronger *c*-axis vertical preferred orientation than high P_{Ar} (A2), as demonstrated by the rocking curve data in Table I. This is expected owing to the lower adatom energy at high P_{Ar} that makes surface transport to the lowest energy position more difficult. A low P_{Ar} nucleation layer followed by high P_{Ar} deposition (A3) produces significantly better orientation than a single high P_{Ar} layer, despite identical conditions for 90% of the deposition.

The small separations between the particles are near the detection limit of high-resolution scanning electron microscopy (HRSEM) under the experimental conditions, but clear differences between samples are nevertheless observable in Fig. 2.

High P_{Ar} CoCrPt deposition (A2) produced a very large (74 nm) feature size (Table I) that may have resulted from the high pressure nucleation process or orientation dependent

FIG. 2. HRSEM images of (a) sample A1 (b) sample A2, and (c) sample A3.

FIG. 3. S_0/N_d and D_{50} of CoCrPt/TiCr media samples.

grain growth. The low pressure (A1) and two-layer (A3) structures have similar particle sizes (43 and 39 nm), owing to their identical nucleation layers.

Magnetically, low $H_{c\perp}$ and relatively high $H_{c\parallel}$ in A2 result from large particles and poorer orientation (Table I). High H_c in A1 and A3 is consistent with a better oriented, small grain structure.

Despite the large particle size, shadowing induced separation at high pressure decreases S_0/N_d of A2 compared to A1, but high density recording performance, as measured by D_{50} reduces (Fig. 3), probably owing to poor orientation and large particles that reduce perpendicular anisotropy H_k . The two-layer sample has higher S_0/N_d and D_{50} than the single layer samples, attributable to small separated particles and only a small loss of preferred orientation with respect to the low P_{Ar} sample.

IV. TiCr NUCLEATION AND GROWTH

Cross-section high-resolution transmission electron microscopy showed multiple renucleation of misoriented ~ 5 nm TiCr grains during 2 m Torr film growth.⁶ Correspondingly, the TiCr {0002} x-ray diffraction peaks are weak and TiCr rocking curves are noisy and quite broad, confirming weak *c*-axis vertical orientation (Table II). CoCrPt {0002} diffraction is much stronger and the rocking curves are much sharper, suggesting that the primary CoCrPt orientation mechanism is not epitaxy. Nevertheless, a low P_{Ar} underlayer (B1) produces better CoCrPt orientation ($\theta_{50}=2.2^\circ$) than a high pressure underlayer ($\theta_{50}\sim 9^\circ$).

For two-layer underlayers, good orientation of the CoCrPt layer is maintained despite brief 35 mTorr growth [$\theta_{50}=2.5^\circ$ for 15 nm and 2.7° for 25 nm (B2)], but is lost after further deposition ($\theta_{50}\sim 9^\circ$ for 45 nm).¹⁰ Some crystallographic information is apparently transferred from the underlayer to the CoCrPt layer and the orientation mechanism, although not determined, seems to be related to both the crystallography of the underlayer and the details of the surface structure.

TABLE II. Group B data.

Sample	CoCrPt θ_{50} (deg)	TiCr θ_{50} (deg)	Particle size (nm)	$H_{c\perp}$ (Oe)	$H_{c\parallel}$ (Oe)
B1	2.2	8.4	43	1850	220
B2	2.7	7.6	61	2040	300
B3	3.5	8.4	38	2560	330

FIG. 4. HRSEM images of (a) sample B1 (b) sample B2, and (c) sample B3.

B2 shows the affect of the nucleation layer upon CoCrPt orientation. B3 shows the effect of changing surface structure. Renucleation in 2 mTorr TiCr occurs every 5 nm (Ref. 6) so B3 should have TiCr surface properties resembling those of the standard film (B1) despite increased particle separation induced by the high pressure underlayer growth.

The B2 and B3 CoCrPt rocking curves ($\theta_{50(B2)}=2.7^\circ$) and ($\theta_{50(B3)}=3.5^\circ$), although broader than the 2 mTorr B1 curve, are both significantly reduced from the $\sim 9^\circ$, value for continued growth at 35 mTorr.

The CoCrPt particle size of B2 is much larger than that for nucleation on the 2 mTorr B1 underlayer (Fig. 4). The particle size of sample B3 is nearly the same as B1, suggesting that the nucleation condition was indeed controlled in large by the template surface.

Magnetically, high $H_{c\perp}$ and low $H_{c\parallel}$ in B2 suggest separated, well oriented particles. Consistently, the large particles reduce D_{50} (Fig. 5), but S_0/N_d is larger than that of B1, as

FIG. 5. S_0/N_d and D_{50} of CoCrPt/TiCr media samples.

expected for improved particle separation.

The combination of small separated particles and strong c -axis orientation in B3 significantly increase $H_{c\perp}$ while maintaining low $H_{c\parallel}$. Correspondingly, there is a large D_{50} and S_0/N_d increase.

V. CONCLUSIONS

Magnetic recording performance of CoCrPt/TiCr sputter deposited perpendicular recording media can be enhanced by independently optimizing the nucleation, growth, and interface microstructures during film growth.

CoCrPt magnetic layers grow columnarly, and can be improved by (a) nucleating oriented grains at low P_{Ar} , and (b) growing oriented, separated columns at high P_{Ar} . Improved orientation was maintained despite 90% of the film thickness being grown at high pressure.

TiCr underlayers do not grow columnarly, but CoCrPt orientation is better for growth on a TiCr surface deposited at low P_{Ar} . An improved underlayer was formed by (a) growing a separated structure at high P_{Ar} and (b) forming a thin low P_{Ar} surface layer for oriented CoCrPt growth.

This preliminary experiment suggests a method to enhance performance of a wide variety of perpendicular and longitudinal recording media.

High recording performance of Co–Cr medium sputter-deposited at high Ar pressure and high substrate temperature

Naoki Honda, Satoshi Yanase, and Kazuhiro Ouchi
AIT (Akita Research Institute of Advanced Technology), Akita 010-16, Japan

Shun-ichi Iwasaki
Tohoku Institute of Technology, Sendai 982, Japan

Co–Cr films were prepared by sputter deposition at a high Ar pressure of 70 Pa with elevated substrate temperatures up to 400 °C. Films of 100 nm thickness were deposited using a 19 at. % Cr–Co target onto a well *c*-axis oriented Ti underlayer prepared on glass disk substrates. The perpendicular coercivity, $H_{c\perp}$, of the films increased from 660 to 1940 Oe with increasing temperature. The films with high $H_{c\perp}$ exhibited a dense fine microstructure with distinct grain boundaries. The recording performance of the disk samples were measured by using a metal in gap type ring head, comparing with that of conventional Co–Cr films deposited at a low Ar pressure of 0.2 Pa. It was found that the high pressure deposited Co–Cr film exhibited higher output by more than 2 dB at the densities below 320 kFRPI (flux reversals per inch) compared with the conventional film with the same high coercivity. The D_{50}^* of as high as 250 kFRPI and the highest recordable density of over 600 kFRPI were confirmed for the new type of Co–Cr film deposited at 70 Pa and at 400 °C. The noise level of the film, however, was slightly higher than that of conventional method films, disagreeing with the suggestion of the microstructure. © 1996 American Institute of Physics. [S0021-8979(96)10008-8]

I. INTRODUCTION

Co–Cr films have been intensively studied as one of the most preferable candidates for ultrahigh density recording media.^{1–3} Recent our work showed that the Co–Cr films deposited at a high Ar pressure with an elevated substrate temperature could have a fine grained dense microstructure with distinct grain boundaries accompanied by a high perpendicular coercivity.⁴ These properties of the films are expected to exhibit a high recording performance with a low noise property when the films are used as perpendicular recording media. In the present article, the effect of the substrate temperature on the magnetic properties and the microstructure of the Co–Cr films deposited at high Ar pressures were studied and the recording properties of the disk samples of such films were measured. A high recording performance of the medium will be discussed.

II. EXPERIMENT

Disk samples were prepared by dc magnetron sputter deposition using 2.5 in. ϕ glass disk substrate. The preparation conditions are listed in Table I. A well *c*-axis oriented Ti underlayer ($\Delta\theta_{50} < 6^\circ$) was first applied onto the glass substrate to obtain a high crystal orientation for the Co–Cr layer. The Co–Cr films of 100 nm thickness were deposited onto the Ti underlayer with substrate temperatures ranging from room temperature up to 400 °C under both high (70 Pa) and low (0.2 Pa) Ar pressures, using a Co–19 at. % Cr target. The sputtering input power was 200 W for the target size of 75 mm in diameter and the target–substrate distance of 55 mm. After the surface was sputter-overcoated with a SiO₂ layer of 10 nm thickness, the recording performances of the disk samples were measured by using a commercial 8 mm VCR's metal in gap type ring head with a gap length of 0.22 μ m. A self-weighted contact head interface⁵ was adopted us-

ing relative head velocities of 1 and 2 m/s for recording and noise measurements, respectively. The magnetic properties were measured by a vibrating sample magnetometer (VSM). A scanning electron microscope (SEM) with a field emission electron gun was used to observe microstructures of the films.

III. RESULTS AND DISCUSSIONS

A. Magnetic properties

Figure 1 shows substrate temperature dependence of the perpendicular coercivity, $H_{c\perp}$, and the in-plane coercivity, $H_{c\parallel}$, for Co–Cr films sputter-deposited at high (70 Pa) and low (0.2 Pa) Ar pressures. When the films were deposited at room temperature, deposition at high Ar pressure resulted in a film with a much higher $H_{c\perp}$ than that of low Ar pressure depositions, as we have reported.⁶ The $H_{c\perp}$ drastically increased with increasing substrate temperature and saturated at high temperatures, yielding a high $H_{c\perp}$ larger than 1800 Oe for both Ar pressure depositions, but the increase in $H_{c\perp}$ for the 70 Pa deposition took place at higher temperatures than for the 0.2 Pa deposition. This may be attributed to reduced kinetic energy of the depositing atoms due to increased number of collisions with Ar atoms at such an extremely high Ar pressure. The in-plane coercivity $H_{c\parallel}$ exhib-

TABLE I. Sputter-deposition conditions for Ti underlayer and Co–Cr layer.

Conditions	Ti layer	Co–Cr layer
Target	99.9% pure	19 at. % Cr–Co
Ar pressure	0.2 Pa	0.2 and 70 Pa
Temperature	Room temp.	Room temp. –400 °C
Film thickness	70 nm	100 nm

FIG. 1. Substrate temperature dependence of perpendicular (L) and in-plane (||) coercivities for Co-Cr films deposited at high (70 Pa) and low (0.2 Pa) Ar pressures.

ited only a small increase with the temperature; this may be attributed to high crystal orientations of Co-Cr layers ($\Delta\theta_{50} < 5^\circ$) which were maintained by the Ti underlayer.

A substantial increase in the saturation magnetization M_s with increasing temperature was observed for the films deposited at 70 Pa, as shown in Fig. 2. The increase of M_s is larger than that of the films deposited at 0.2 Pa. This suggests development of some Cr microsegregation in the films with the elevated temperature, although our previous study on the microsegregation in the films by using chemical etching suggested that Cr microsegregation is less in the grains.⁴

B. Microstructure

An SEM observation of the film surface, shown in Fig. 3, revealed that when the films were deposited at a high Ar pressure of 70 Pa, a channeled structure of the film deposited at room temperature [Fig. 3(a)] changed to a dense structure with distinct grain boundaries with increasing substrate temperature [Fig. 3(b)]. Further elevation of the temperature resulted in small increase in the grain size, suggesting coalescing of the grains [Fig. 3(c)]. The growth of the grains may be caused by increased mobilities of adatoms on the surface by the elevated temperature. On the other hand, films deposited

FIG. 2. Substrate temperature dependence of saturation magnetization M_s for Co-Cr films deposited at high (70 Pa) and low (0.2 Pa) Ar pressures.

FIG. 3. SEM images of film surfaces for Co-Cr films deposited at high (70 Pa) and low (0.2 Pa) Ar pressures with different substrate temperatures.

at 0.2 Pa exhibited much larger grain growth with increasing temperature, but showed minute change in grain boundary structure, which still remained dense and faint [Figs. 3(d) to 3(f)].

C. Recording performances

Figure 4 shows recording density response for the Co-Cr disk samples deposited at a Ar pressure of 70 or 0.2 Pa and at the highest substrate temperature of 400 °C. Both disks exhibited the highest perpendicular coercivities at each Ar pressure. Reproduced output for the disk medium deposited at 70 Pa was higher by about 2 dB than that of the medium deposited at 0.2 Pa at the recording densities below 320 kFRPI, which corresponds to the second peak density in the response. Although the medium deposited at 70 Pa exhibited reduced output at higher densities over 400 kFRPI, the half output density for the envelope response D_{50}^* of as high as 250 kFRPI and the highest recordable density of over 600 kFRPI were obtained.

A small degradation in the perpendicular anisotropy of the present film may be one of the causes for the above high recording performance. The same improvement in recording

FIG. 4. Recording density dependence of normalized output for Co-Cr films deposited at high (70 Pa) and low (0.2 Pa) Ar pressures.

FIG. 5. Perpendicular coercivity dependence of normalized pulse height for Co-Cr films deposited at high (70 Pa) and low (0.2 Pa) Ar pressures.

performance is reported for recording on evaporated Co-Cr films with a ring head,⁷ in which the increase in output is explained in terms of a small increase in in-plane anisotropy.

The isolated pulse height increased with the coercivity increase for both media deposited at the high and low Ar pressures, as shown in Fig. 5. It is also indicated that the high pressure deposited media exhibit higher output by 1–2 dB than the low pressure deposited media at the same coercivity. However, the high output property of the medium would be diminished by the higher noise level of the film, which is shown in Fig. 6 as the coercivity dependence of the dc erased noise level integrated for 1 to 8 MHz (which corresponds to the wavelength of 0.25 to 2 μm). The SEM image seen in Fig. 3 indicates smaller grain size for the film deposited at 70 Pa [Fig. 3(c)] than the film deposited at 0.2 Pa [Fig. 3(f)], suggesting lower noise level for the medium deposited at the high Ar pressure. The higher saturation magnetization M_s , seen in Fig. 2 could be the cause of the increased noise level. The exact reason of the higher noise level for the media is not clear at present. Further investigation is required.

IV. SUMMARY

Co-Cr disk samples were prepared by sputter deposition at a high Ar pressure of 70 Pa with elevated substrate temperatures.

FIG. 6. Perpendicular coercivity dependence of dc erase noise level for Co-Cr films deposited at high (70 Pa) and low (0.2 Pa) Ar pressures.

The perpendicular coercivity of the films increased from 660 to 1940 Oe with increased temperature. The high coercivity films exhibited a dense fine microstructure with distinct grain boundaries. The evaluation of the recording performance by using a ring head revealed that the high pressure deposited Co-Cr film provides a higher output by about 2 dB at densities below 320 kFRPI than the low pressure deposited film with the same high coercivity and the thickness. Although the noise level of the film could not be improved, the D_{50}^* of as high as 250 kFRPI and the highest recordable density of over 600 kFRPI were obtained for the film deposited at 70 Pa and at 400 $^{\circ}\text{C}$.

Microwave solitons in magnetic films (invited) (abstract)

A. D. Boardman, K. Xie, and H. Mehta

Joule Laboratory, Department of Physics, University of Salford, Salford, M5 4WT, England

S. A. Nikitov

Institute of Radio Engineering and Electronics, Russian Academy of Sciences, 11 Mokhovaya St., 103907, Moscow, Russia

Nonlinear waves in the form of solitons in magnetic films are attracting attention because of the interesting possibility of making novel spatial, and temporal, soliton devices that will operate in the technologically important microwave (GHz) frequency window. Some fascinating pioneering experimental work has been performed in this area and there is now every possibility that manipulation of solitonlike microwave pulses will be the basis of an entirely new range of devices.¹ Both theory and experiment show that solitons are extremely robust and behave rather like particles. Magnetic films look set to become as successful as optical fibers in supporting bright envelope solitons; yet soliton behavior can often seem hard to comprehend. While they are subtle in their behavior they can be understood from many points of view that are physically, or mathematically, based. This presentation will explain what bright microwave envelope solitons are, drawing upon as much physical insight and analogy as possible. The necessary and sufficient conditions for soliton existence will be carefully set out, especially with respect to their relationship to the input conditions of a device. A substantial number of numerical examples will be used and the prospects for major expansion in the experimental area will be assessed. In the latter part of the presentation some important applications for solitons will be addressed. These will include the analysis of a switching device but logic devices, and various forms of pump-probe arrangements, will also be retrieved. Finally, the optimistic view that solitons in magnetic materials are now realistic tools will be expressed and the opportunities provided by dark and higher-dimensional solitons will be discussed. © 1996 American Institute of Physics. Thresholds of spin wave envelope soliton formation in magnetic films with dissipation (abstract)

A. N. Slavin^{a)}

Oakland University, Rochester, Michigan 48309

The nonlinear mechanism responsible for the spin wave envelope soliton formation in magnetic films from input pulses of finite duration is the four-wave process with conservation law $\omega(k_0) + \omega(k_0) = \omega(k_0 + \kappa) + \omega(k_0 - \kappa)$, $\kappa \ll k_0$. This process is also responsible for modulation instability of CW wave in a nonlinear dispersive medium and can only take place if the nonlinearity N and the dispersion D in the medium have opposite signs. In a dissipative medium this process has a finite amplitude threshold determined by the dissipation parameter γ and the effective "detuning" $\Delta\omega$ proportional to the dispersion D and the square of the modulation wave number κ ,^{1,2} $|\varphi|_{\text{th}}^2 = [\gamma^2 + (\Delta\omega)^2/4]/|N\Delta\omega|$, hereafter referred to as Eq. (1), where $|\varphi|$ is the dimensionless wave amplitude. For the process of modulational instability of a CW wave $\Delta\omega = D\kappa^2$. For the process of soliton formation from a finite input pulse (of the duration T) $\Delta\omega = D\kappa_n^2$, where $\kappa_n = (2n-1)\pi/vT$, n is the number of solitons formed, and v is the group velocity of spin waves. Equation (1) gives a good description of the recent measurements of thresholds of spin wave envelope soliton formation in YIG films presented in Ref. 3. In particular, describes correctly the shape of the threshold curve, positions of threshold minima for the formation of one and two solitons, and explains the finite intercept on the threshold power dependence on the inverse square of the input pulse duration that was not explained in Ref. 3. © 1996 American Institute of Physics. Phase properties of microwave magnetic envelope dark solitons in yttrium iron garnet thin films (abstract)

J. M. Nash, P. Kabos, C. E. Patton, and R. Staudinger

Department of Physics, Colorado State University, Fort Collins, Colorado 80523

Although microwave magnetic envelope (MME) solitons in thin yttrium iron garnet (YIG) films have been studied extensively, only recently have dark MME solitons been observed.¹ For a single dark soliton, one has a carrier phase change of 180° . Reference 1 indicated such a change. However, the overall phase change for a given dark pulse experiment should be 0° . The objective of this work was to examine phase profiles in detail for the dark soliton experiment. The results show that both of the above expectations are, in fact, satisfied. The 5 GHz measurements were done with a magnetostatic wave delay line structure with a long and narrow $7.2\text{ }\mu\text{m}$ thick single crystal YIG film oriented in the surface wave configuration. A GaAs microwave switch produced 300 ns long bright pulses separated by a dark pulse with a width in the 15 ns range. The input power was 0.002–1.0 W. The output signal showed two main dark pulse features, independent of power level. At low powers, the changes in phase across both features were small. With increasing power, the phase change across the first feature showed a rapid increase while the phase change for the second feature remained small. The phase change for the first feature saturated at a large value, on the order of 200° , relative to the phase change at low power. The phase change over the entire profile was always 0° . These results show: (1) There are significant phase changes at both low and high powers in the dark pulse experiment. (2) The phase change for a dark soliton must take into account the background phase change at lower powers. (3) Only the main dark pulse feature in the output profile exhibits single dark soliton characteristics through a clearly resolved phase saturation at 180° . (4) These thresholds are on the order of 10 mW for typical strip line transducer structures, compared to 100 mW or so for bright solitons. © 1996 American Institute of Physics. Two-dimensional solitons in the classical Heisenberg antiferromagnet with nonmagnetic impurities

Kala Subbaraman, Craig E. Zaspel, and John E. Drumheller
Department of Physics, Montana State University, Bozeman, Montana 59717

Experimental evidence is presented for the existence of nonlinear localized spin excitations (solitons) in the classical two-dimensional Heisenberg magnet doped with nonmagnetic impurities. These solitons are shown to provide the dominant mechanism for spin relaxation in electron paramagnetic resonance linewidths immediately above the ordering temperature for layered Mn compounds with a small impurity concentration. The new gapless excitations are pinned by the nonmagnetic impurities thereby becoming topologically unstable and lower in energy than the nonlinear excitations (skyrmions) that may exist in the pure material. Concentration-dependent results preclude a spin-wave mechanism for this effect. © 1996 American Institute of Physics. [S0021-8979(96)72308-2]

INTRODUCTION

It has been assumed that the thermodynamic quantities, such as the spin correlation functions, of lower dimensional magnets are determined by the spin wave spectrum. Recent work, however, on nonlinear excitations has shown that they have a much different effect on correlation functions than the spin waves. These effects lead to possible methods of experimentally detecting nonlinear excitations. For example, Mertens *et al.*¹ have shown that mobile vortices give rise to a central peak in the dynamic spin correlation function, and similarly, we have shown that a central peak will result from moving solitons.² Waldner^{3,4} was the first to suggest that solitons were indirectly observed in the Arrhenius behavior, $\exp(E_s/T)$, of the temperature-dependent electron paramagnetic resonance (EPR) linewidth in layered antiferromagnets, (AFMs). It was assumed that E_s was the soliton excitation energy, but at that time there was no linewidth calculation showing that this temperature dependence should be expected.

More recently⁵ we have calculated the temperature-dependent EPR linewidth due to solitons, with the result that solitons indeed dominate the dynamic spin correlation function in the classical two-dimensional (2D) AFM. This dominance is seen as an Arrhenius temperature dependence. The solitons are of the static type first predicted by Skyrme⁶ and applied to the 2D magnet by Belavin and Polyakov.⁷ Structurally, these excitations correspond to a mapping of the spin sphere onto the lattice sphere with a constant magnetization far from the soliton center. In this article we will report the experimental results of the effect of doping (*n*-propylammonium)₂ tetrachloro-manganese(II) (PAMC) with nonmagnetic impurities on the EPR linewidth. It is shown that owing to the lower energy, solitons pinned by the very small impurity concentrations (less than 1%) will significantly affect the temperature-dependent EPR linewidth.

EXPERIMENTAL DETAILS

EPR experiments were performed with PAMC because it is a good example of a classical isotropic 2D Heisenberg AFM.⁸ This is a layered compound with MnCl_4^{2-} layers well separated by a bilayer of the hydrocarbon chains, resulting in

a very small interlayer to intralayer coupling ratio $J'/J \approx 10^{-5}$. The doped samples were grown by slow evaporation of a solution of propylammoniumchloride and manganese chloride and cadmium or zinc chloride in ethanol. It was noted that the Zn concentrations present in the single crystals were roughly an order of magnitude lower than the amount that went into the solution while the opposite effect was observed in the case of cadmium. Faint pink platelets were obtained with masses varying from 2 to 5 mg. The dimensions of these crystals were roughly $5 \times 5 \times 0.2 \text{ mm}^3$ with the smaller dimension corresponding to the *b* axis. From the powder susceptibility data on pure PAMC⁹ it was estimated that about 0.1% of Mn^{2+} ions are present as paramagnetic impurities. Extreme care was taken in growing the crystals since the paramagnetic impurities present were comparable to the dilution strengths. Cd concentrations were determined using atomic absorption spectroscopy while Zn concentrations were measured using gravimetric analysis. The uncertainty in the chemical analysis varies from 5% at $x=0.001$ to 25% at $x=0.01$.

RESULTS AND DISCUSSION

EPR data were obtained with an X-band spectrometer for the pure Mn compound, as well as for $(\text{nPA})_2\text{Mn}_{1-x}\text{Zn}_x\text{Cl}_4$ with $0.001 < x < 0.01$ and $(\text{nPA})_2\text{Mn}_{1-x}\text{Cd}_x\text{Cl}_4$ with $0.001 < x < 0.08$. At room temperature the compounds exhibited similar angular- and temperature-dependent ERP linewidths, with characteristics of 2D spin diffusion.¹⁰ Lowering *T* from room temperature toward the AF transition the linewidth initially decreases until a minimum is reached at approximately 70 K. At temperatures near T_N ($T_N = 39.2 \text{ K}$) a rapid increase in linewidth ΔH is observed for all concentrations.¹¹ The exponential rise of ΔH as T_N is approached is the part of the data illustrating 2D soliton behavior. Figure 1 shows a plot of $\ln(\Delta H)$ vs T_N/T for the temperature range $1.2T_N \leq T \leq 1.5T_N$ for $x=0$, $x=0.004$, and $x=0.0106$ for the Zn-doped crystals. Figure 2 shows a similar plot for the Cd-doped crystals. Below $T_N/T=0.9$ the linewidths continue to broaden so severely that the measurement of ΔH becomes less certain. Linewidth measurements were made on three crystals with similar concentrations and the average E_s cal-

culated in each case. Figure 3 is a plot of E_s vs x and shows a steady decrease in soliton excitation energy with an increase in the impurity concentration.

The ac susceptibility measurements were made on a few larger single crystals with $0.001 < x < 0.05$. For such low dilution strengths there was no change observed in T_N or the exchange constant J as a function of Zn or Cd concentration. This precludes the possibility of a variation in T_N causing the observed effect.

The data were compared with theoretical calculations of the excitation energy in Ref. 11. The comparison indicated a

FIG. 3. The decrease of the soliton excitation energy as the percentage of impurity concentrations is increased. \circ —data for Zn-doped samples, \bullet —data for Cd-doped samples.

discrepancy of an order of magnitude. This disagreement is not surprising in view of the limitations of the theory presented in that article. In the magnetic vortex problem¹² it is found that the vortex structure is strongly affected by the discreteness of the lattice, especially near the core. Large solitons, in general, can be described by a continuum field, as was done in Ref. 11. For small solitons, the discreteness of the solitons becomes important at small distances from the core, and have to be taken into consideration when determining the spin dynamics.

It was also observed that the discrepancy between theory and the data is more pronounced in the case of Zn-doped crystals than the Cd-doped ones. This seems to indicate clustering effects, which will result in a larger measured x . Clustering lowers the effective concentration since a cluster may be taken to be a single site for a static excitation, and so this would enhance the observed effect if it is present in any large degree. The chemistry of the crystals, which appears to depend on the type of dopant used, is not clearly understood. Errors in the chemical procedures used to produce the dilutions are the most likely source of error, though great care was taken to avoid this situation.

CONCLUSION

Both experimental and theoretical investigations of the EPR strongly indicate the dominating role of nonlinear localized excitations in the thermodynamics of the 2D isotropic Heisenberg magnet PAMC. While the introduction of nonmagnetic impurities into such a sample has rendered the nonlinear solutions observable by creating a gapless energy spectrum,¹¹ there also exists a strong concentration dependence from which has been used to distinguish the nonlinear effect from that of spin waves. However it is not clear how the presence of nonmagnetic impurities will affect the spin dynamics of the solitons in detail. Further theoretical work,

which includes the discrete nature of the lattice near the core, is necessary for a better understanding of the critical dynamics of the 2D magnets.

Interaction of light with a nonlinear spin wave in a normally magnetized ferromagnetic film

A strong collinear magneto-optical interaction of guided light with an intensive forward volume spin wave (SW) has been studied in a normally magnetized film. A numerical perturbation technique has been developed to quantify the effects, which accompany the optical diffraction. Extensive numerical simulations of the magneto-optical diffraction by the SW affected by nonlinear automodulation were carried out. The parameters of interaction related to automodulation mechanisms were varied within a wide range of values, covering most practical situations. Specifically, the automodulation frequency assumed values of $1 \text{ MHz} < F < 100 \text{ MHz}$, and the index of phase modulation, linear in modulation instability threshold, the values of $1 < \nu < 4$. © 1996 American Institute of Physics. [S0021-8979(96)72408-9]

INTRODUCTION

In the last decade it has been demonstrated that high efficiency can be achieved in the light-spin wave (SW) magneto-optic interactions.¹⁻³ Intensive SWs used in the experiments manifest strong nonlinearity,⁴⁻⁶ including amplitude instability.⁴ This transforms the spectrum of an initially sinusoidal SW into a multifrequency one. However, thus far theoretical work has been restricted to diffraction of light by a linear purely sinusoidal SW. This article addresses the analytical and numerical theory of the interaction of light with a nonlinear multifrequency SW in a normally magnetized film.

THEORY

First, a purely sinusoidal intensive SW is excited in a ferromagnetic film and, due to the nonlinearity, it is transformed into a multifrequency one. At the second stage, an optical waveguide mode traveling in the same film is diffracted by a phase grating induced by the now multifrequency SW medium through magneto-optical effects. These stages take place sequentially. We consider below a case when a finite amplitude sinusoidal forward volume spin wave (FVSW) is initially excited in a perpendicularly magnetized film.

We restrict attention to the case when only the four-wave interaction processes determine the nonlinear properties. Further we use the theory of four-wave SW instability developed in Ref. 7 and later applied to a ferromagnetic film.⁸ As shown in Ref. 9, in the case of continuous excitation the nonlinear equation describing the SW behavior leads to the modulational instability of a monochromatic SW propagating in a film. Assuming a narrow packet of SWs (central in-plane wave vector \mathbf{Q}_0 , central frequency ω_0 , and amplitude b_0) linearly excited in a film, the conservation laws for the four-wave interaction process take the form $2\omega_0 = \omega_1 + \omega_2$, $2\mathbf{Q}_0 = \mathbf{Q}_1 + \mathbf{Q}_2$.

The instability increment ν for the above process, described by an equation of motion for the SW amplitudes of the two nonlinearly generated harmonics, is given by Refs. 7 and 10: $\nu^2 = -D\kappa^2(D\kappa^2 + 4N|b_0|^2)/4$, where N is a coefficient

of the four-wave Hamiltonian, describing nonlinear coupling between SWs. We denoted $\mathbf{Q}_1 = \mathbf{Q}_0 + \kappa$ and $\mathbf{Q}_2 = \mathbf{Q}_0 - \kappa$, assuming without loss of generality that $\kappa \ll Q_0$ and κ is collinear to \mathbf{Q}_0 . Also a Taylor series expansion for the SW dispersion characteristic was utilized, defining $v_g = (\partial\omega_Q/\partial Q)_{Q=Q_0}$ and $D = (\partial^2\omega_Q/\partial Q^2)_{Q=Q_0}$. For a medium with dissipative parameter ω_r , the squared instability increment must be larger than the square of the dissipation parameter $\nu^2 \geq \omega_r^2$, which leads to the threshold formula:

$$|b_{n0}|_{\text{th}}^2 \geq \frac{\omega_r^2 + (D\kappa^2)^2/4}{|ND|\kappa^2}. \quad (1)$$

The threshold calculated from Eq. (1) is shown in Fig. 1 by a solid line, while the broken line shows the threshold in a lossless medium. It follows that the threshold of modulational instability has a minimum value $|b_0|_{\text{th min}}^2 = \omega_r/|N|$ for the instability having the characteristic wave number $\kappa_m = (2\omega_r/|D|)^{1/2}$ and frequency $F_m = v_g \kappa_m/2\pi$.

When the minimum threshold is exceeded by the factor $\zeta = |b_0|^2/|b_0|_{\text{th min}}^2$, the range of possible modulation frequencies is $\zeta - (\zeta^2 - 1)^{1/2} < (F/F_m)^2 < \zeta + (\zeta^2 - 1)^{1/2}$. The modulation frequency at the threshold can be easily estimated using the data¹¹ for a typical experiment on FVMSW in a YIG film (thickness $h = 7.2 \text{ } \mu\text{m}$), yielding $F_m = 49.5 \text{ MHz}$. When the supercriticality is $\zeta = 2$, which corresponds to a SW power of

FIG. 1. Threshold of modulational instability in a dissipative medium.

approximately 50 mW, the possible modulation frequencies satisfy $25 \text{ MHz} < F_m < 95.5 \text{ MHz}$. However, the value of D can change considerably. For example, in the vicinity of a dipole-exchange gap it increases by at least one order of magnitude.¹² In our numerical simulations we therefore vary the SW automodulation frequency from 1 to 100 MHz to cover typical situations.

The optical part of the problem is as follows. A monochromatic optical waveguide mode (incident wave or zero diffraction order) is excited in the ferromagnetic film in a direction parallel to that of an intensive multifrequency SW. Due to the magneto-optic interaction the incident light wave is partially converted into an optical mode of orthogonal polarization (diffracted wave or first diffraction order). We restrict our attention to the collinear geometry which is most promising for optical frequency shifters. Such devices require high diffraction efficiency and SWs of elevated intensity.

To solve the diffraction problem we have selected the perturbation approach described in detail in Ref. 13. The amplitude in the first diffraction order is expanded as

$$A_s(\omega) = \sum_{m=0}^{\infty} (v)^m A_s^m(\omega), \quad (2)$$

where $v = \beta \Delta n L$ is the index of phase modulation. The convergence of the series (2) is discussed in detail in the next section. Here β is the light wave number *in vacuo*, Δn is the perturbation of refractive index of the film induced by the SW, and L is the interaction length.

NUMERICAL RESULTS

Our numerical simulations are consistent with a real magneto-optical experiment.¹⁻⁷ In particular, the interaction length is 5 mm. The spectral transformations resulting from our simulations are illustrated in Fig. 2. An initially excited SW is represented by just one harmonic [Fig. 2(a)]. Due to the nonlinearity of the SW, two additional harmonics are generated which describe the process of amplitude modulation. We assume that the rate of modulation, i.e., the ratio of the sideband and central frequencies, $a = 0.5$ [Fig. 2(b)].

As $F \rightarrow 0$ the optical Bragg condition has no effect on the diffraction process. The perturbation approach allows us to consider the magneto-optical diffraction as a multiple-scattering process. For weak interaction (such that $v \ll 1$), the onefold scattering is predominant. In this case the optical spectrum duplicates that of a nonlinear SW without distortion. However, for $v > 1$ scattering of higher multiplicity has to be taken into account. Mathematically n -fold scattering corresponds to a nonlinear operation of n -fold autoconvolution of the SW spectrum. In particular, additional harmonic multiples of F are generated. Such nonlinear spectral distortions, with the increase of v , are illustrated in Fig. 2(c)–2(f). The results in Fig. 2 are graphically indistinguishable from those for the case $F = 1 \text{ MHz}$. In our calculations we retained nine terms in series (2), ensuring an accuracy exceeding the graphic resolution.

With increasing F many scattering mechanisms are prohibited because of the optical Bragg condition. The effect on

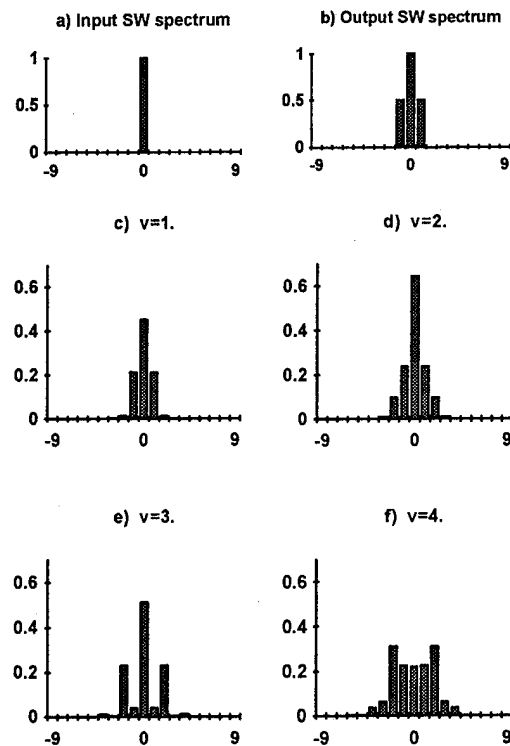

FIG. 2. Spectral transformations in the course of (a), (b) nonlinear SW automodulation; (c)–(f) magneto-optical interaction (in the $F \rightarrow 0$ limit).

the diffracted light spectrum is illustrated in Figs. 3(a), 3(b), 3(d), 3(e), 3(g), and 3(h). The horizontal scale is the multiplicity number of an optical harmonic. Figures 3(c), 3(f), and 3(i) show the amplitudes of the main optical spectral components as functions of v . Curve 0 corresponds to the zero-harmonic amplitude $A(f)$ (due to the initial monochromatic SW), curve 1 corresponds to the first-harmonic amplitude $A(f+F)$ (due to the nonlinearity of the SW system), curve

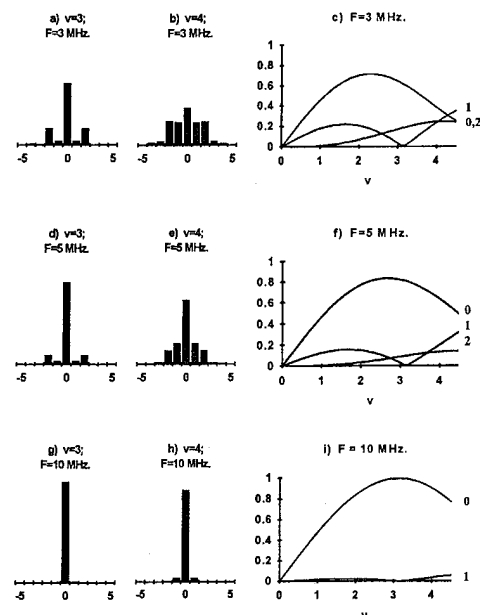

FIG. 3. Optical spectra for different values of automodulation frequency: (a)–(c) $F = 3 \text{ MHz}$; (d)–(f) $F = 5 \text{ MHz}$; (g)–(i) $F = 10 \text{ MHz}$.

FIG. 4. Frequency performance of optical spectral components $A(0)$ (curve 0), $A(1)$ (curve 1), and $A(2)$ (curve 2).

2 corresponds to the second-harmonic amplitude $A(f+2F)$ (the first additional harmonic which is due to the nonlinear character of the diffraction distortion). With the growth of F one can concentrate almost all optical power (up to 99%) in the zero harmonic which is very important for potential applications. Also, for large values of ν the additional "spurious" harmonics are still noticeable, which is equally important for optical devices. The corresponding amplitudes as a function of the nonlinear modulation frequency F are presented in Fig. 4. The value of ν is chosen to be 3, i.e., in the vicinity of the point of maximum diffraction efficiency [see Figs. 3(c), 3(f), and 3(i)]. The amplitude $A(f+2F)$, which is due mainly to higher order scattering, declines more rapidly than $A(f+F)$. By adjusting ν to be close to π we can minimize $A(f+F)$. However, this will have no noticeable effect on $A(f+2F)$, which means that to keep the level of spurious harmonics below 60 dB we must ensure $F > 60$ MHz.

The above results are presented in terms of ν , which is implicitly related to the SW amplitude through the quantity Δn . With the development of new materials with elevated values of magneto-optical constants²⁻⁴ Δn can vary significantly for identical SW amplitudes. Numerical estimates

show that SW amplitude automodulation threshold levels (tens to hundreds of mW) induce Δn values in a film consistent with $1 < \nu < 4$.

CONCLUSION

When considering the interaction of guided light with an intensive SW, one should take into account the effect of the nonlinear SW automodulation and multifrequency aspects of the subsequent optical diffraction. In a normally magnetized film this can cause the generation of two spurious harmonics, which corresponds to an amplitude modulation of a FVSW with a frequency $1 \text{ MHz} < F < 100 \text{ MHz}$. The perturbation approach proved to be effective in numerical simulations of the optical spectrum of the diffracted light. High accuracy is ensured, even for very strong interactions ($\nu \approx 3-4$), by retaining nine terms in the expansion. An increase in F minimizes the diffraction-related distortions of the optical spectrum. For a typical situation, when the rate of SW amplitude modulation $a = 0.5$ the condition $F > 10 \text{ MHz}$ ensures that over 99% of the energy will be concentrated in the zero harmonic. However, it is not easy to entirely suppress higher order harmonics. For example, it is only for $F > 60 \text{ MHz}$ that the level of the second harmonic falls below 60 dB.

Variations in auto-oscillation frequency at the main resonance in rectangular yttrium-iron-garnet films

A. Prabhakar

D. D. Stancil

Electrical and Computer Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

High power microwave experiments conducted on a rectangular yttrium-iron-garnet (YIG) film indicate a parabolic dependence of the square of the frequency of auto-oscillations on microwave signal amplitudes, an observation that is qualitatively consistent with prior theoretical predictions. Forward volume magnetostatic waves were excited using a microstrip transducer kept in contact with a YIG film placed in a constant external magnetic field ($H_{dc}=3.48$ kG). Variations in the input microwave power ($10 \text{ dBm} < P < 25 \text{ dBm}$) and frequency ($5.1 \text{ GHz} < f < 5.7 \text{ GHz}$) were used to locate and study auto-oscillations close to the Suhl instability at the main resonance. A novel method of viewing changes in the microwave passband using density plots enables us to study variations in the dipole gaps in the passband near the Suhl instability. A broadening of dipole gaps into fingerlike regions of weak transmission marks the onset of auto-oscillations beyond the instability threshold. These regions are associated with a variety of spin-wave dynamics ranging from simple auto-oscillations to auto-oscillations with period doubling and in some cases an abrupt transition to a turbulent wide-band power spectrum. The parabolic dependence of the auto-oscillation frequency persists despite a period-doubling bifurcation. © 1996 American Institute of Physics. [S0021-8979(96)72508-5]

I. INTRODUCTION

Modulational instabilities at high microwave power levels have been previously studied in thin yttrium-iron-garnet (YIG) films¹ and in YIG spheres.^{2,3} These studies indicate that the frequency of auto-oscillation (AO) increases monotonically with an increase in the amplitude of the microwave signal. Using the center-manifold theory on the entire degenerate spin-wave manifold, Zhang and Suhl⁴ calculated the frequency of the limit cycle associated with the AO and predicted that the square of the frequency would vary in a parabolic manner with an increase in the microwave signal amplitude. Our experimental observations on a rectangular YIG film are qualitatively consistent with these predictions. Careful measurements taken at the main resonance, close to the second Suhl instability (SI) threshold, reveal that the parabolic behavior persists even when the system undergoes a period-doubling bifurcation. However, as also noted by various authors,²⁻⁵ depending on the exact input parameters it is possible to follow a route to chaos where the frequency of AO appears to merely increase monotonically and the spin-wave manifold undergoes an abrupt transition to turbulence without observing the parabolic behavior predicted theoretically.

The ferromagnetic resonance (FMR) measurements by McMichael and Wigen on circular YIG films⁶ indicate the existence of fingerlike regions of AO associated with the standing wave magnetostatic modes in low-power FMR spectra. In our experiments on propagating waves in rectangular YIG films at high power, we observed the emergence of similarly shaped fingers that corresponded to regions of weak transmission. A wide variety of chaotic dynamics, including AO, were visible in the fingerlike regions. By monitoring the changes in the microwave passband with increases

in microwave power, we note that the fingers are associated with the broadening and shifting of the dipole gaps in the passband. The use of density plots to display the data enables us to map the regions of weak transmission over a wide range of input parameters ($10 \text{ dBm} < P < 25 \text{ dBm}$ and $5.1 \text{ GHz} < f < 5.7 \text{ GHz}$).

II. EXPERIMENTAL RESULTS

Our experiments were carried out on a rectangular YIG film ($5 \text{ mm} \times 10 \text{ mm} \times 7.4 \text{ } \mu\text{m}$). Separate low power FMR measurements on the film indicate a linewidth of 0.9 Oe at 9.2 GHz suggesting a decay rate of 1.27 cm^{-1} . A constant magnetic field, $H_{dc}=3.48$ kG, was applied perpendicular to the film plane and spin-waves were excited using a microstrip transducer in contact with the film. A second transducer, 3 mm from the first, picks up the output signal from the device and feeds it to a spectrum analyzer where the AO appear as secondary peaks surrounding the primary input frequency. The frequency of AO is calculated as the average separation between adjacent peaks in the output spectrum. Figure 1 shows the variation of the AO frequency as a function of input signal amplitude both with and without a period doubling bifurcation. The signal amplitude was calculated at the input terminals of the device after accounting for cable losses and the reflected power. The parabolic nature of the variation in frequency is qualitatively consistent with the theoretical predictions by Zhang and Suhl.^{4,7} A quantitative comparison of the experimental and theoretical results would involve (a) estimating the decay constants and coupling coefficients associated with interacting modes, (b) modeling the microstrip geometry to calculate the amplitude of the rf field and (c) reformulating the center-manifold theory to in-

FIG. 1. Variations in the square of AO frequency with increasing microwave signal amplitudes. (a) Simple parabolic dependence and (b) parabolic dependence with a period doubling bifurcation. Both sets of data have been fit to binomial expressions to facilitate comparisons.

clude the dependence of the coupling coefficients and decay constants on the mode number, tasks that are beyond the scope of this article.

We observe a wide range of AO frequencies depending on the location of the input signal frequency in the microwave passband. As one approaches the top of the parabola, the spin-wave system attempts to follow one of various competing routes to chaos. While this attempt manifests itself as a small deviation from the parabolic behavior in the curve of Fig. 1(a), the curve of Fig. 1(b) demonstrates a case of period doubling with the formation of a limit-two cycle, where the system returns to its original limit cycle after further increases in signal amplitude. Very often, as we increase the

FIG. 2. Transmission characteristics of the YIG film. The passband was obtained with a device input power of -24 dBm in the presence of an external field $H_{dc}=3.48$ kG. The arrows mark the frequencies at which the two sets of data in Fig. 1 were taken.

input power, we see an abrupt transition to turbulence near the top of the parabola. Such behavior is reminiscent of attractor destruction when, as the power reaches a critical value P_c , the attractor collides with the stable manifold of an unstable periodic orbit (boundary crisis). Carroll, Pecora and Rachford⁵ have reported similar observations in their experiments on YIG spheres near the first Suhl instability. They also provide a description of the overlapping basins of attraction for chaotic and nonchaotic attractors in the spin-wave system that can explain the deviations from the parabolic dependence that we sometimes observe.

A typical microwave passband measurement using a network analyzer with a device input power of -24 dBm is shown in Fig. 2. The dipole gaps in the passband are due to the pinning of spin-waves on the surfaces of the film.^{8,9} Figure 2 also shows the location in the passband where the measurements in Fig. 1 were made. By replacing the network

FIG. 3. (a) Density plot of the passband obtained by stepping the input power between 10 and 25 dBm in steps of 0.2 dBm. The frequency scale is accurate to within 1.2 MHz. The white areas correspond to regions of weak transmission. The density is proportional to $P_{\text{transmitted}}/P_{\text{incident}}$, normalized on a scale of 0 to 10. (b) An inset that shows the emergence of global patterns associated with weak transmission (patterns similar to the fingers of AO). The cross-hairs mark the regions where the data in Fig. 1 were obtained.

analyzer with an amplifier and a diode detector, and sending the output to a digital oscilloscope, we observe changes in the passband at much higher power levels ($10 \text{ dBm} > P > 25 \text{ dBm}$). Figure 3 is a density plot of the passband over a region of frequency-power phase space. The density is linearly proportional to transmitted power divided by power incident on the device, with black corresponding to maximum transmission. The y-scale shows the raw incident power at the device and has not been corrected for any reflections from the input port. The dipole gaps in the passband, which at low power appear as thin white lines, eventually broaden into wider regions with weak transmission characteristics. These broad white regions reveal very complex routes to chaos while their edges approximately mark the onset of AO. Similar contiguous regions of AO have previously been referred to in the literature as fingers of AO.⁶ Although the orientation of the regions of weak transmission in Fig. 3 appears to be different from that of the fingers of AO reported by McMichael and Wigen,⁶ when we keep H_{dc} constant and sweep the frequency, we are actually mapping regions in phase space similar to theirs. The measurements of the AO frequency were made at the edges of the white regions, presumably in areas having fewer interacting spin-wave modes. The cross-hairs in Fig. 3(b) reveal the exact locations in phase space where the AO measurements were taken. The marked difference in the parabolic dependence seen in Fig. 1 appears to be a result of experiments conducted at different locations in parameter space, possibly in different fingers of AO. There is a shift in the bottom of the passband ($\approx 10 \text{ MHz}$) similar to the frequency shift observed in experiments on magnetostatic wave delay lines.^{10,11} Measurements of the reflected power indicate that the waviness in the white pattern visible at high frequencies is due to reflections from the input port of the device. These reflections cause variations in the actual power coupled into the spin system. However, the broadening of dipole gaps that leads to the formation of regions of instability is a nonlinear phenomenon that does not appear in a density plot of the reflected power. The various features that appear in the density plots for transmitted power (Fig. 3) and reflected power are currently under investigation.

III. CONCLUSIONS

The onset of AO at the main resonance was observed experimentally. The square of the frequency of AO followed a parabolic dependence on the input signal amplitude in a manner consistent with theoretical predictions. The exact location in frequency-power phase space where the measurements were possible was determined using density plots of the microwave passband. It was found that the dipole gaps in the passband broaden out and shift toward higher frequencies, eventually forming wide regions of weak transmission. Since these regions are fairly rich in a variety of routes to chaos, the measurements on AO frequency were made at their edges. The parabolic dependence is observed even when the spin-wave system undergoes a period doubling bifurcation. The exact nature of the dependence varies with the location in parameter space.

The density plots of the transmitted power have revealed a global absorption pattern similar to the fingers of AO. There is also a frequency shift in the entire passband that could be a combination of thermal and nonlinear effects.

ACKNOWLEDGMENTS

We would like to express our gratitude to Dr. J. D. Adam for supplying the YIG film used in these experiments. This research was supported in part by the National Science Foundation under Grant No. ECS-9206817.

Driven spin-wave dynamics in yttrium-iron-garnet films (abstract)

D. J. Mar, T. L. Carroll, L. M. Pecora, J. F. Heagy, and F. J. Rachford

Naval Research Laboratory, Washington, DC 20375

Yttrium-iron-garnet (YIG) is an important component used in filters and other microwave devices. In this work we investigate the behavior of driven magnetostatic wave modes in rectangular YIG films subject to an in-plane magnetic field. Patterned slotlines and coplanar waveguides are used to drive the film at separate spatial locations with microwave (2–4 GHz) excitations corresponding to the magnetostatic wave modes. For a single excitation with sufficient power above the Suhl instability, the transmitted power through the film displays periodic low-frequency (10 kHz) auto-oscillations. As the drive amplitude is increased, these oscillations may display period-doubling, intermittency, and high-dimensional behavior, including chaos. A second microwave drive applied to the sample excites additional spin-wave modes that interact with those arising from the original excitation. These interactions result in additional low-frequency components in the observed auto-oscillations. © 1996 American Institute of Physics. [S0021-8979(96)68808-1]

Synchronization of chaos in circular yttrium iron garnet films

D. W. Peterman, M. Ye,^{a)} and P. E. Wigen

Department of Physics, The Ohio State University, Columbus, Ohio 43210

The results of the synchronization of two ferromagnetic resonance signals are presented. In the experiment, a thin yttrium iron garnet (YIG) film was placed in the perpendicular resonance configuration and the bias field, rf power, and frequency were chosen so that the rf absorption of the YIG sample was chaotic. A segment of this chaotic signal was stored into memory. The goal was to induce the sample to synchronize to its prerecorded output through a perturbation applied to a system parameter. The results of these synchronization experiments were predicted by a numerical model. © 1996 American Institute of Physics. [S0021-8979(96)72608-1]

INTRODUCTION

To synchronize two chaotic signals appears to be a daunting task, since any small discrepancies in the signals are predicted to diverge rapidly. However, it has been shown theoretically that chaotic signals can be synchronized with the appropriate coupling¹⁻³ and chaotic synchronization has been realized in several experiments.^{1,4-9} Secure communications are a possible application of the phenomenon. This report will present results of synchronization in ferromagnetic resonance (FMR) involving thin yttrium iron garnet (YIG) disks.

High power FMR studies involving YIG have a long history of experimental¹⁰⁻¹² and theoretical^{13,14} activity in nonlinear and chaotic dynamics. For the results presented here, a YIG disk 2 mm in diameter and 1 μm was immersed in a magnetic field oriented perpendicular to the film plane. A perpendicular uniform rf pumping field at 1.2 GHz generated by a slot line structure¹⁵ excited the magnetostatic modes in the sample. A diode detected the reflected rf fields, which allowed for the rf absorption of the sample to be determined. At low rf powers, smooth, well-defined peaks in the magnetostatic mode spectrum are observed. In circular YIG films, the magnetostatic modes take the form of Bessel functions. As the rf power is increased, certain regions of the magnetostatic spectrum develop a periodic ac absorption component (auto-oscillation) superimposed upon the dc absorption component. This ac component is due to the nonlinear dipole interactions between the magnetostatic modes in the sample. Further increasing the rf power above the auto-oscillation threshold often leads to an ac absorption displaying a bifurcation route to chaos.^{10,11,13} The frequencies associated with the auto-oscillations and chaos are in the range of 0.5–10 MHz.

EXPERIMENT

In the experiment, the magnetic field and rf frequencies were chosen so that the sample absorption possessed a chaotic ac component. A segment of the chaotic FMR signal was recorded into memory. A small 20 turn coil 1.5 cm in diameter oriented parallel to the film plane was suspended 2 mm above the sample to perturb the bias magnetic field. In a

previous experiment, it was found that time-delayed perturbations to the sample bias field were able to control the chaotic behavior of the YIG sample.¹⁶ The goal of this experiment was to perturb the bias magnetic field to induce the real time signal to follow its prerecorded output.

In synchronizing FMR signals, some of the previously proposed synchronization techniques cannot be implemented due to the nature of the FMR experiment. For example, Carroll and Pecora (CP),¹ in theory and experiment, demonstrated that the decomposition of a chaotic system into coupled drive and response subsystems will synchronize if the response system has only negative Lyapunov exponents. Another method of chaotic synchronization has been proposed by Lai and Grebogi (LG).² Their method does not require decomposition of the system, but involves a continual complex calculation of the coupling parameter. In our FMR experiment, a uniform rf driving field couples to all the magnetostatic modes, and therefore the FMR dynamical system cannot be decomposed, as required by CP. In addition, the submicrosecond time scales in the FMR dynamics do not allow a computationally intensive parameter perturbation such as the one proposed by LG.

For these reasons, the perturbation to the bias field required to synchronize the FMR signal to its prerecorded output was proportional to the difference between the prerecorded FMR signal and real-time FMR signal,

$$\delta H_{\text{bias}} = K(V_{\text{master}} - V_{\text{slave}}). \quad (1)$$

In the above equation, V_{master} refers to the prerecorded FMR signal, V_{slave} refers to the real-time FMR signal, and K is an experimentally determined proportionality constant. This synchronization scheme is similar to the one proposed by Pyragas,³ and has been proven successful in previous experiments.⁶⁻⁹

When the sample bias field was perturbed in accordance with Eq. (1), the difference between the master and slave signal was reduced by more than an order of magnitude. The difference between the master and slave signal was reduced to approximately the noise level in the experiment within about 10 μs . This transient behavior when the control is applied is shown in Fig. 1. In Fig. 2, a delay coordinate plot of the FMR slave signal during synchronization is presented, indicating the chaotic nature of the dynamics during synchronization. The perturbation fields required to achieve synchronization are small. In the initial transient, the perturba-

FIG. 1. The difference between the master and slave in the experiment. At $t=0$, the two signals are synchronized by the parameter perturbations. At approximately $10 \mu\text{s}$, the stored signal loop restarts, creating a discontinuity time master signal, resulting in a divergence of the two signals. The parameter perturbation cause the signals to reconverge in about $10 \mu\text{s}$.

tion is no greater than 1 Oe. After the initial transient, fields in the 0.01–0.1 Oe range are required to maintain the synchronization. When the synchronization control was removed, the sample dynamics instantly began to diverge from the prerecorded signal. This synchronization effect has been observed in several chaotic regions of this and other samples.

The effectiveness of the synchronization appeared to be somewhat insensitive to the proportionality constant K . While there indeed existed a window of K values in which synchronization was achievable, the upper limit of this window was often 2–4 times the value of the lower limit. Below this window, the two signals were observed to follow a pattern of nearly similar trajectories for a few microseconds interspersed by periods of divergence in the two signals. As K was increased and approached the lower bound of the synchronization window, the divergences reduced in severity

FIG. 2. Delay coordinate plot in arbitrary units of the FMR slave signal's attractor during synchronization ($\tau=50 \text{ ns}$).

FIG. 3. Difference between the master and slave in the numerical model. The synchronization perturbations are switched on at $t=10 \mu\text{s}$.

and in duration. When K was increased above the upper limit of the synchronization window, the master signal was over corrected and was consistently divergent from the slave signal.

While a wide range of K values were able to maintain synchronization, the ability to synchronize the two signals was quite sensitive to differences in the experimental conditions responsible for the master and slave signals. This suggests that when the prerecorded signal and YIG sample dynamics arise from the same underlying attractor, the YIG sample is easily induced to follow its prerecorded output. However, when the prerecorded output and YIG sample dynamics have slightly different underlying attractors, i.e., changes in the magnetic bias field, the sample is resistant to follow the dynamics of a different attractor, even if this difference is slight.

NUMERICAL MODELING

A theoretical model of FMR developed by McMichael and Wigen¹² was used for numerical simulations of the observed synchronization. The complex magnetostatic mode amplitudes were determined by integrating the coupled nonlinear equations of motion in this model. The FMR signal in the model was proportional to the sum of the imaginary parts of the mode amplitudes, which corresponds to the rf absorption in the experiment.

To model the experimental results, the numerical parameters were chosen to lie in a chaotic regime and a chaotic time series segment of the FMR signal was captured. This stored signal corresponds to the master signal in the experiment. The simulation was run again. The FMR signal was continuously compared with a random segment of the stored chaotic time series, and the static magnetic field was perturbed proportional to this difference between the signals, as in Eq. (1). Figure 3 shows the two signals synchronize in 5–10 μs , and the difference of the signals approaches zero, in agreement with the experimental results. However, different random master segments require different transient times,

with 5–10 μ s being typical. Transient times as long as 30 μ s have been observed.

The numerical modeling displays a similar insensitivity to the K observed in the experiment. In addition, changes in the numerical parameters of a few percent reduce the synchronization effect by at least a factor of 10. This roughly corresponds to the high sensitivity of the synchronization scheme to differences in the underlying experimental conditions of the master and slave signals observed in the experiment.

CONCLUSION

Two chaotic FMR signals have been synchronized through a perturbation applied to a system parameter, the static bias field of the YIG sample. The perturbation is proportional to the difference between the real-time FMR signal and a prerecorded signal. The FMR signals that are synchronized possess frequency components in the 0.5–10 MHz range, making these chaotic dynamics the fastest ever synchronized to the authors' knowledge. While the dynamics of the system are well modeled, the underlying equations of motion can remain unknown in this synchronization scheme. A more quantitative and physical understanding of the de-

pendence of the synchronization to K and to differences in the underlying master and slave attractors appears to be a promising future direction of this research.

Experimental observation of the longitudinal resonance mode in ferromagnets with random anisotropy

G. Suran and E. Boumaiz

Laboratoire de Magnetisme et Optique de Versailles, CNRS, Meudon 92195, France

J. Ben Youssef

LMIMS, CNRS, Meudon 92195, France

We report here the first experimental observation of the longitudinal resonance mode in ferromagnets with a wandering axis (FWA). The mode is detected in amorphous $\text{Co}_{93-x}\text{Zr}_7(\text{RE})_x$ thin films with $\text{RE}=\text{Pr}, \text{Nd}, \text{Tb}$, and Dy , $0 \leq x \leq 4$, but only if the film exhibits a very well defined in-plane uniaxial anisotropy field H_k . The experimental identification and some of the main properties of the longitudinal mode are reported and compared with theoretical predictions.

© 1996 American Institute of Physics. [S0021-8979(96)72708-8]

I. INTRODUCTION

A considerable amount of experimental and theoretical work has been performed on ferromagnets which possess a random anisotropy (FRA). One of the main questions raised was if these systems will exhibit dynamical properties the behavior of which is essentially controlled by the random anisotropy. Several theoretical suggestions were advanced,¹⁻³ but were not followed by experimental observations.

Here we report a completely new resonance phenomenon which can be observed only in FRA: We detected experimentally for the first time the so-called longitudinal resonance (LR) mode and for the transverse configuration, the localized transverse resonance (TR) mode. One of the chief reasons which previously prevented this experimental discovery is that these modes can be discerned only on compounds having specific properties. The structure of the article is the following: First we expound a brief theoretical review of the physics of magnetic resonance. Then the experimental data are reported and discussed. To begin we expose the properties of compounds in which the LR and TR modes could be detected, followed by the main magnetic properties of the LR mode.⁴ Some of the main features of the LR and that of the uniform resonance obtained on the same sample will be compared directly. It is a highly instructive way to illustrate the peculiarities of the LR mode.

II. THEORETICAL REVIEW

The magnetic properties of an amorphous solid—which is by definition a FRA—are determined by the same two main magnetic parameters as those of crystalline solids: Exchange A and magnetic anisotropy energy. The properties reported hereafter are essentially determined by the local anisotropy constant K_l .⁵ The effect of randomness upon A will be neglected. Such approximations are fairly usual in this area.

The new resonance modes have been detected on thin films which are ferromagnets with weak random anisotropy (FWRA), i.e., $H_r < H_{ex}$, $H_r = 2K_l/M_s$, $H_{ex} = 2A/M_s R_a^2$, and $R_a \approx 10 \text{ \AA}$ is the structural correlation length. In conformity with theoretical analysis⁶ a FWRA presents several magnetic regimes according to the strength of the external

field H . If H is smaller than a critical field H_s , the long-range magnetic regime is destroyed and the material exhibits a correlated spin glass (CSG) regime. If $H > H_s$, the system has a significant moment with a slightly noncollinear structure, the so-called ferromagnet with wandering axis (FWA). A FWA regime is attained if the system also possesses a coherent uniaxial anisotropy.

Ferromagnetic resonance (FMR) is a well understood phenomenon in crystalline compounds. As a result of the strong exchange force the spins forming the magnetization M_s maintain a perfect parallelism when a steady field H is applied. The static equilibrium direction of M_s , M_s^{eq} , is oriented along the effective field determined by the various magnetic energies of the system, and M_s precesses coherently around M_s^{eq} . However because of the existing damping, the precession motion has to be maintained by applying a high frequency rf field h_{rf} perpendicular to M_s^{eq} with $|h_{rf}| \ll |H|$. A so-called collective (or uniform) resonance occurs when the frequency of this transverse h_{rf} is equal to the precession frequency of the system, the field for resonance being determined by the classical Kittel formula. Until now only this collective mode has been detected in amorphous systems.

Now let us consider the physics of FMR in a FRA.² If K_l is neglected, using the proposed approximation one finds a perfect ferromagnetic alignment of the spins along H . If K_l is considered, as this anisotropy energy does not have any preferred direction, the neighboring spins will slightly reorient themselves and will not be exactly collinear anymore. Consequently the equilibrium direction varies from site to site, so the rotation of the spin system about any axis leads to a restoring torque. One way to take into account this effect in the computation is to include a spin-space rotation angle about the magnetization vector as a dynamical variable. This hypothesis is extremely important from a conceptual point of view, because it assumes that the random anisotropy is metastable so it can change direction during the precession. It follows from the overall computation that one finds a LR^2 and a TR mode.²

In the LR mode the equilibrium state of M_s (M_s^{eq}) is parallel to the h_{rf} field. The condition for resonance can be expressed in terms of the longitudinal macroscopic anisotropy strength, i.e., the anisotropy associated with a uniform

rotation of the system around the axis parallel ($K_{||}$) to the average magnetization. The mode is a dissipative one so it presents a peculiar relaxation mechanism.

III. EXPERIMENTAL RESULTS

A. Properties of the compounds

Among the highly different amorphous compounds which we studied by FMR until now, the LR and TR modes could be detected on amorphous $\text{Co}_{93-x}\text{Zr}_7(\text{RE})_x$ thin films where $\text{RE}=\text{Nd}, \text{Pr}, \text{Dy}, \text{Tb}$ and for the concentration range $0 < x < 4$.^{7,8} The films were prepared by rf cosputtering. The Zr is incorporated in order to obtain a well-defined amorphous state even for such low RE concentration. The structure was controlled experimentally.

Moreover a necessary condition to be satisfied is that the films exhibit an in-plane anisotropy field $H_k = 2K_u/M_s$. On magnetically isotropic thin films or films which display perpendicular anisotropy, the LR and TR modes could not be detected. H_k was formed by applying a dc magnetic field $H_d = 700$ Oe in the film plane during deposition. The full mechanism is described elsewhere.⁸

B. LR mode: Experiments and discussion

The magnetic properties were determined by B-H loop tracer and transverse biased initial susceptibility (TBIS) measurements.⁹ Whatever the RE was substituted for, the whole concentration range is $10^4 \text{ Oe} \leq 4\pi M_s \leq 1.2 \times 10^4 \text{ Oe}$, where $4\pi M_s$ decreases for higher RE contents. These compounds are soft ferromagnets as confirmed by the small coercive field H_c , typically in the range of $0.5 \text{ Oe} \leq H_c \leq 3 \text{ Oe}$.⁶⁻⁸

FMR investigations were performed using a commercial 9.8 GHz spectrometer with a TE_{011} cavity. The spectra were obtained by changing the orientation of H with respect to the film plane, and also by varying the angle between h_{rf} and the easy axis. Here we report results obtained when the mode exhibits a pure longitudinal character—the case where $\theta \leq 10^\circ$. The properties of the LR mode are practically the same for the various RE substituted. The results will be illustrated by those obtained for $\text{RE}=\text{Tb}$.

Let us consider the case $\theta = 0^\circ$, i.e., H is applied perpendicular to the film plane (Fig. 1). On all samples one detects the collective resonance, the main properties of which were reported previously.⁶ The field for resonance is typically in the range $1.4 \times 10^4 \leq H_{\perp} \leq 1.6 \times 10^4 \text{ Oe}$ with H_{\perp} decreasing with increasing RE content. The variations of the resonance linewidth ΔH_{\perp} are also characteristics: ΔH_{\perp} increases linearly as a function of increasing RE concentration and its magnitude is determined by the particular RE substituted. The properties of the collective mode are independent of the existence and/or the definition of H_k .

Apart from the collective mode another mode has been detected on a large number of samples, which can be formally identified as the LR mode. An extremely strict condition that the LR mode could observe is that the in-plane uniaxial anisotropy field H_k is very well defined. One can easily show both by computation and by experimental investigations, using TBIS or observation of the domain structure,

FIG. 1. Typical derivative absorption spectra with the applied dc field being perpendicular to the film plane (H_{\perp}): (a) Collective (uniform) resonance, (b) LR mode. The modes were detected with the same sensitivity. h_{rf} is parallel to the easy axis.

that the H_k imposes a FWA magnetic regime. So a necessary condition which must be satisfied so that the LR can be detectable is that the samples exhibit a FWA regime. The properties of the LR are determined by the definition of H_k which can be studied by two different techniques: Visual inspection of the $B-H$ loop along the hard axis, and quantitatively by TBIS⁹ measurements: TBIS allows one to separate without any ambiguity the intrinsic fluctuations of M_s related to K_l , the so-called ripples, from the long-range dispersion of H_k , the skew.⁹

First we review the characteristics of the LR mode obtained on films where the skew is negligible. The field for resonance is $H_{\perp}^{\text{LR}} = 1100 \pm 150 \text{ Oe}$. H_{\perp}^{LR} is independent of the nature, or the concentration of the RE and apparently fluctuates randomly. One has $H_{\perp}^{\text{LR}} \leq 4\pi M_s$, consequently the magnetization of the film lies practically in its plane (M_s comes out from the film plane with an angle of about 3° – 5°), so the demagnetizing field can be considered as negligible. In these conditions one can be tempted to compare the experimental results with the theoretical formula established for a FWA with negligible demagnetizing field,³

$$\omega = 2\gamma(H^3 H_{\text{ex}})^{1/4}. \quad (1)$$

If one takes, for $H_{\text{ex}} = 2.5 \times 10^5 \text{ Oe}$, the value obtained with $A = 10^{-6} \text{ ergs/cm}^3$ and $M_s = 800 \text{ emu/cm}^3$, the computation gives $H \approx 300 \text{ Oe}$. The difference between this H and H_{\perp}^{LR} could be related to several factors: Equation (1) was not established for a thin film which possesses a H_k and the particular configuration of the experiment (H_{\perp}) could also affect the results.

Equation (1) predicts a rather unusual $H^{3/4}$ dependence of the longitudinal resonance frequency. We tried to verify it by performing measurements using a variable-frequency spectrometer. In Fig. 2 we present the magnetic field at resonance as a function of spectrometer frequency f . The observed variations are effectively extremely regular, but these data do not allow us to determine definitely if f follows a $H^{3/4}$ or a linear law versus H . H_{ex} deduced from the fitting of the $H^{3/4}$ curve is $H_{\text{ex}} = 2 \times 10^3 \text{ Oe}$, a value which is much

FIG. 2. Variations of the resonance field, H_{\perp} of the LR mode vs frequency f in a typical sample. The data are compared with a linear and a $H^{3/4}$ fitting.

smaller than the expected one. $\Delta H_{\perp}^{\text{LR}}$ was found to be independent of f and for the reported sample it is $\Delta H_{\perp}^{\text{LR}} = 160 \pm 10$ Oe.

The longitudinal nature of the mode could be proven formally by studying its variation as a function of α . While the values of the field for resonance H_{\perp}^{LR} and that of the linewidth $\Delta H_{\perp}^{\text{LR}}$ are effectively strictly independent of α , the microwave power absorbed at resonance, contrary to the collective resonance, varies extremely strongly with α and follows closely the law (Fig. 3)

$$P(\alpha) = P(0) \cos^2 \alpha, \quad (2)$$

where P is the absorbed microwave power and $P(0)$ corresponds to $h_{\text{rf}} \parallel H_k$. The magnitude of h_{rf} is fairly small. Consequently whatever the orientation of h_{rf} , M_s is practically aligned along H_k which is its equilibrium direction. One can conclude that P is maximum for $\alpha = 0^\circ$ or when $h_{\text{rf}} \parallel M^{\text{eq}}$. Therefore the mode is longitudinal. Consequently, in agreement with a computation reported elsewhere, for a linearly polarized microwave field the variations of $P(\alpha)$ vs α are given by Eq. (2). The residual value of P for $\alpha = 90^\circ$ could be related to the fact that the experiments are performed with a field applied perpendicular to the film plane.

FIG. 3. Variations for $\theta = 0^\circ$ and $\theta = 10^\circ$ of the localized resonance mode intensity as a function of α . The solid line is a curve computed using the expression $I = P(\alpha)/P(0) = \cos^2 \alpha$. (■, ○): experimental data.

FIG. 4. Variations of the derivative resonance linewidth corresponding to the collective (ΔH_{\perp}) and LR ($\Delta H_{\perp}^{\text{LR}}$) mode, respectively, as a function of Tb content.

The particular nature of the mode is also confirmed by the unusual properties of the corresponding resonance linewidth $\Delta H_{\perp}^{\text{LR}}$ (Fig. 4). $\Delta H_{\perp}^{\text{LR}}$ seems to be independent of the nature and/or the amount of the substituted RE and fluctuates in the range of 80–200 Oe. Its value appears to be essentially related to the determination of H_k , but one cannot exclude the contribution of other actually unidentified parameters. This independence of $\Delta H_{\perp}^{\text{LR}}$ from the magnetic properties and the concentration of the RE is a highly unusual behavior and could be related to the dissipative nature of the mode: It could be explained by the rotatable precession of the random anisotropy.

A comparison of the absorbed microwave power corresponding to the collective and LR modes, respectively, shows that, contrary to the collective mode to which all magnetic spins contribute, only a limited number of spins participate in the LR. This amount can be estimated from $N \sim I_1 \Delta H_1^2 / I_2 \Delta H_2^2$ where I is the intensity and the suffix 1 corresponds to the LR mode. N fluctuates randomly in the range $1/20 < N < 1/7$. A possible hypothesis to explain this result is that only those spins contribute to the LR mode that have an easy axis oriented closely to H_K .

Electron spin resonance on single crystals of the spin-Peierls compound CuGeO_3 has been performed in magnetic fields up to 17 T in the temperature range 1.8–20 K. Using far-infrared laser frequencies of 245 and 525 GHz we could observe resonance conditions in the three different magnetic phases, i.e., the uniform, the dimerized, and the incommensurate phases for a magnetic field applied parallel to the a axis of the crystal. So for the first time data on electron spin dynamics in the incommensurate phase are reported for fields far from the transition to the dimerised phase. Striking effects concerning the g factor, linewidth, and hysteresis are observed. © 1996 American Institute of Physics. [S0021-8979(96)72808-4]

The phase diagram of the inorganic compound CuGeO_3 has recently been shown to follow rather well the predictions for a “spin-Peierls” system.¹ In such a model, three magnetic phases can be defined.² There is the uniform (U) phase which essentially describes the behavior of $s=1/2$ isotropic Heisenberg antiferromagnetic (AF) chains, the dimerized (D) phase observed at low temperatures, and an incommensurate (I) phase which can only be achieved in the presence of a strong magnetic field. Applying the far-infrared electron spin resonance (ESR) technique to CuGeO_3 , we have been able to probe elementary excitations in these three different phases.

CuGeO_3 has an orthorhombic structure with a space group $Pbmm$. The AF chains are formed by the $S=1/2$ Cu^{2+} ions running along the c axis of the crystal. In the U phase, the exchange interaction along the chains has been assumed to be of the isotropic Heisenberg type $\mathbf{H}=J_c \sum_i \mathbf{S}_i \mathbf{S}_{i+1}$ with $J_c \sim 100$ K.¹ In the D phase, interchain couplings along the b and a axes have also been evaluated, yielding $J_b \sim 10$ K and $J_a \sim -1$ K, respectively.³ Concerning its magnetic properties, CuGeO_3 can be regarded as a quasi-one-dimensional spin system. Samples used in the present study were grown from the melt by a floating zone technique.⁴ The phase diagram for such a crystal is shown in Fig. 1 for a magnetic field (H) applied along the a direction. This diagram has been determined from magnetization (M) measurements, the points corresponding to maxima in the susceptibility $\chi \sim \partial M / \partial H$.⁵ In zero field, the lattice dimerization is seen to occur at $T_{sp} \sim 14$ K and the critical field H_c , which determines the first-order transition between the D and I phases, is $H_c \sim 12.5$ T. All these results agree well with the determination made initially by Hase *et al.*⁶ The electron spin resonance (ESR) measurements to be discussed below were obtained also for H applied parallel to the a axis. The resonance conditions were achieved by transmitting electromagnetic waves—provided by an infrared laser—through the sample in Faraday geometry and by sweeping the magnetic field. In the present work, very thin crystals (about 0.2 mm in the a direction) have been used in order to avoid possible artefacts due to interference effects which can occur when the wavelength of the transmitted light becomes smaller than the

thickness of the sample. This could well explain the differences we observed with previous results. In particular, unlike what was reported in Ref. 7 for the D phase, no additional structure in the ESR line—see Figs. 1 and 2 in Ref. 7—is now observed when the temperature is increased. With such a thin crystal, we always found a single resonance line in the temperature range 4.2–20 K, and for fields up to 17 T.

The temperature dependence of the integrated intensity (I) of the ESR absorption allows one to distinguish ground state excitations from transitions between excited states. In the latter case, the observed behavior has to be compared with the temperature dependence calculated for a population difference between the initial and final states governed by Boltzmann statistics for instance. Finally, a fitting procedure of such a model with the data can provide an evaluation of the gap value between the ground state and the initial state of the transition. For the ESR absorption observed at 245 GHz/8.1 T, we extended the previous investigation presented in Ref. 7 down to 1.8 K. Figure 2 shows the experimental values of I and the result of the fitting procedure (the solid line). With this procedure the gap in zero field is evaluated to be $\Delta = 23.5$ K in excellent agreement with neutron data.³ In Fig. 2, the deviation observed between the data and the curve above 7 K can be attributed to the renormalization of the energy gap as $T \rightarrow T_{sp}$, which for this field value is $T_{sp} \sim 13$ K. Above T_{sp} , i.e., in the U phase, the ESR line is expected to have a different origin. It results from transitions from the ground state and can be considered as describing the “uniform” mode of the continuum of excitations known to characterize Heisenberg AF chains. Remarkably, no drastic change in shape and position of the ESR line is observed at the transition between the D and U phases. This is clearly seen in Figs. 3(a) and 3(b), where the ESR linewidth (ΔH) and the g factor of the 245 GHz/8.1 T resonance are given as a function of temperature. For ΔH (full width at half-maximum) a minimum is observed at about 7 K, as already reported in Ref. 8 for the neighboring frequency of 232.3 K. However, compared to that work, the values that we obtained for ΔH are appreciably smaller, $\Delta H \sim 22.5$ mT at 20 K, against $\Delta H \sim 50$ mT in Ref. 8. Similarly, important differ-

FIG. 1. Phase diagram of CuGeO_3 , for H parallel to the a axis of the crystal, defining the uniform (U), the dimerized (D), and the incommensurate (I) phases.

ences are also obtained for the g factor. Between 20 and 5 K, the observed decrease of g is of the order 0.2% five times less than in Ref. 8. These important differences might be due to the fact that all the measurements reported in the present work have been performed on very thin crystals. Finally it is worth mentioning the change in the variation of g which occurs at low temperature: below 5 K, surprisingly g starts to increase again.

FIG. 2. Integrated intensity (I) of the ESR absorption spectra for the 245 GHz/8.1 T resonance as a function of temperature. The solid line is a theoretical curve according to Boltzmann statistics (see the text).

FIG. 3. The linewidth ΔH and g factor of the 245 GHz/8.1 T resonance as a function of temperature.

In the U phase, the application of a strong magnetic field results essentially in a broadening of the linewidth. This is easily seen by comparing the two resonances—245 GHz/8.1 T and 525 GHz/17.4 T. At 8.1 T, between 15 and 20 K, the g factor and the linewidth stay almost constant [see Figs. 3(a) and 3(b)]. For 17.4 T the g factor is the same as for 8.1 T, but the linewidth is strongly increased: $\Delta H \sim 58$ mT at 17.4 T, compared to $\Delta H \sim 20$ mT at 8.1 T. The interesting point now is to follow the ESR line through the transition between the U and I phases, and to explore the I phase. Figure 4 shows the ESR spectra obtained at $H \sim 17$ T. Due to a field modulation technique, the recorded signals correspond to derivatives of transmission spectra. Signal 4(a) was obtained at 16 K, i.e., in the U phase, signal 4(b) at 10 K which is practically the spin-Peierls temperature for that field value, and signal 4(c) at 8 K, i.e., in the I phase. Except for a small narrowing, no drastic change is seen on the ESR line when one goes from the U phase to the I phase. However, lowering the temperature below ~ 7 K, i.e., going further in the I phase, a remarkable hysteresis effect is observed. As shown in 4(d), the ESR line now depends drastically on whether the transmission spectrum (the frequency of the electromagnetic wave is constant) is taken with increasing or decreasing field.

The changes concern the line shape, the linewidth, and the line position. For the 525 GHz/17.4 T resonance at $T = 4.2$ K, the linewidths are $\Delta H \sim 62$ mT for fields going up (solid line) and $\Delta H \sim 55$ mT for fields going down (broken line). The hysteresis effect is also seen on the center of the

FIG. 4. Derivatives of transmission spectra recorded at the fixed frequency of 525 GHz, for different temperatures. At 4.2 K, the hysteresis effect is clearly observed: the solid and broken lines correspond to increasing and decreasing fields, respectively.

line which is shifted by about 100 G ($\Delta g/g \sim 0.06\%$). Finally, at such high fields, we observed that the integrated intensity increases when the temperature is lowered. This result suggests that, in the *I* phase, the ESR line corresponds to transitions induced from the ground state.

As shown in the present work, the high field far-infrared (ESR) technique allows us to probe the spin dynamics in the different phases of the spin-Peierls system CuGeO_3 . We have shown that at such high frequencies, the size of the sample might be a crucial point. The features described here are

certainly more reliable, in particular with respect to their quantitative evaluation. In the *D* phase, two types of transitions can be observed, from the ground state and between excited states associated with the triplet of the spin-Peierls gap.⁷ For that case, the variation observed in the *g* factor is worth noting. It can be attributed to slight changes in the lattice structure. This can be well understood at T_{sp} where the lattice is known to dimerize. However, the new increase observed at low *T* is more surprising: it shows that the lattice of CuGeO_3 is very sensitive to thermal effects even in the *D* phase. In the *U* phase, the ESR signal is attributed to an elementary excitation of the spin system. The linewidth is strongly field dependent. Is this effect related to the magnetic incommensurability which is predicted to develop in Heisenberg AF chains in a field?⁹ In the *I* phase, we have shown for the first time that, even far from the *D*–*I* transition, hysteretic behaviors can be observed. A more complete analysis of this remarkable effect has to be done. Anyhow, it shows that, in the *I* phase, the crystallographic structure of CuGeO_3 is also very sensitive to the applied magnetic field.

Naval Research Laboratory, Washington, D. C. 20375

Magnetic anisotropies of a 357-Å-thick Co film in the bcc phase were examined using Brillouin light scattering. This film, one of the thickest known bcc Co structures, is found to have a fourfold magnetic anisotropy that is markedly different from those of thinner films. A large possibly strain-induced uniaxial anisotropy is also found. The film is thick enough so that the surface and $n=1$ bulk magnon are within a few GHz of each other and strongly hybridize. Unusual behavior of the scattering intensities suggest the possible presence of surface anisotropies and/or inhomogeneous internal fields. © 1996 American Institute of Physics. [S0021-8979(96)72908-0]

Stabilization of fcc and bcc phases of Co can be accomplished by epitaxial growth on suitably chosen substrates.^{1,2} The bcc structure is interesting because it is predicted to be a true metastable state having a large exchange splitting between majority and minority spin bands.³ Experimental determination of magnetic properties in bcc Co films therefore provide useful data for comparison to theoretical models. Also, in a true metastable phase the lattice constant should be independent of film thickness with no distortions of the crystal due to competition between the bulk and interfacial strain energies. The magnetic properties should then be uniform throughout the film, although they may differ from those of the bulk material. In this article we present measurements of anisotropies in a thick bcc Co (357 Å) film, one of the thickest known bcc Co structures, and discuss possibilities for inhomogeneities in the internal effective fields.

At present, theoretical work on magnetic properties has concentrated on exchange splittings and magnetic moments^{4,5} with calculations of magnetic anisotropies reviewed in Ref. 6. From the experimental side, large uniaxial anisotropies have been observed in a 202-Å-thick bcc Co (110) film.⁷ This is surprising in that the cubic symmetry of the bcc lattice suggests that the lowest order magnetocrystalline anisotropies should have fourfold symmetry. In a previous paper⁷ we used measured values for elastic constants to argue for a magnetoelastic origin of the uniaxial anisotropies in this 202-Å-thick bcc Co film. A fourfold anisotropy was not observed in this film although a small negative fourfold anisotropy was found in a (100) grown bcc Co film.⁷ Our present results for the 357 Å bcc film indicate a larger negative fourfold anisotropy in addition to a large uniaxial anisotropy.

The sample was a single-crystal 357 Å film of bcc Co grown on GaAs (110) by molecular beam epitaxy.¹ The bcc structure was confirmed by x-ray diffraction and extended x-ray-absorption fine structure studies.⁸ Brillouin spectra were taken in backscattering with 5145 Å laser light using the same setup as described in Ref. 7. The angle of incidence was 30°. The specimen was rotated in order to change the orientation of the applied field (H_0) relative to the crystal axes so that the plane of incidence was always normal to the

direction of H_0 . The magnetization of the film was determined with a superconducting quantum interference device magnetometer.

The theory used to fit the Brillouin data is discussed in detail in Refs. 9–11 and is a generalization of the work by Camley and Mills⁹ to include anisotropies and arbitrary in-plane orientations of the magnetization with respect to H_0 . In brief, a free energy containing the Zeeman energy of the static magnetization M_s in field H_0 , a uniaxial in-plane anisotropy energy K_u , a uniaxial out-of-plane anisotropy energy K_p , and a fourfold anisotropy energy K_1 is minimized to determine the equilibrium orientation of M_s . For the (110) film, the free energy has the form¹²

$$E^{(110)} = -H_0 M_s \sin \theta \cos(\phi_H - \phi) + \frac{K_1}{4} \left\{ \cos^4 \theta + \sin^4 \theta [\sin^4 \phi + \sin^2(2\phi)] + \sin^2(2\theta) \times \left(\cos^2 \phi - \frac{1}{2} \sin^2 \phi \right) \right\} - K_u \sin^2 \theta \cos^2 \phi + K_p \cos^2 \theta + 2\pi M_s \cos^2 \theta,$$

where θ and ϕ are equilibrium angles of M_s measured with respect to the film normal and the [001] axis, respectively. ϕ_H is the angle of H_0 measured with respect to [001]. The frequencies for the spin waves are found in the long wavelength limit from torque equations⁹ constructed using the above energy and linearized with respect to small fluctuations about the equilibrium orientation. The magnetostatic limit is assumed and exchange interactions are accounted for via an effective field $(2A/M_s^2)\nabla^2 \mathbf{m}$ where A is the exchange constant. Plane wave solutions are assumed with an in-plane wave vector k_{\parallel} . The perpendicular wave vectors are determined from the equation of motion together with exchange and electromagnetic boundary conditions.

Spin wave frequencies and scattering intensities were measured in three different series of experiments: as a function of field along an easy direction [001]; as a function of field along a hard direction $[\bar{1}10]$; and as a function of orientation angle ϕ_H at fixed applied magnetic field strength. The surface and two lowest order bulk modes referred to as “S”, “ B_1 ”, and “ B_2 ” were visible for this film thickness. Magnetization measurements gave the value 14.3 kG for

FIG. 1. Magnetic field (H_0) dependence of spin wave frequencies (S , B_1 , and B_2). The frequencies of modes when H_0 is along the hard axis $[110]$ are shown and the inset shows when H_0 is parallel to the easy axis $[001]$. The 5145 \AA radiation was backscattered at an angle of incidence of 30° in both cases. The dotted lines are fits to the data.

$4\pi M_s$, and was used in our fits. The exchange constant A , gyromagnetic ratio g , and anisotropies K_u , K_p , and K_1 were chosen to provide the best fits to all the data. Each parameter controls a different aspect of the spin wave frequencies and the individual effect of each parameter can to a large extent be identified in the experiments. For example, the quantity A controls the frequency difference between the B_1 and B_2 modes. For this M_s , A was found to be $1.4 \times 10^{-6} \text{ ergs/cm}$.

Spin wave (S , B_1 , B_2) frequencies as a function of H_0 applied in the $[001]$ direction are shown in the inset of Fig. 1. The frequencies increase approximately linearly with field. The dotted lines are calculated fits using the analysis described above. The slope is controlled by the gyromagnetic ratio g . We used the value 2.1 which also reproduces the slope at high fields for the data shown in the main Fig. 1 where H_0 is now along $[110]$. The low field structure in Fig. 1 is due to the rotation of the magnetization away from the easy direction $[001]$. The magnetization is entirely along the hard direction for field strengths greater than 2.4 kOe. This is also consistent with the saturation field found from hysteresis loop measurements.¹ The saturation field coincides with a slight dip in the spin wave frequencies in Fig. 1. The magnitude of this field equals $2(K_u - K_1)/M_s$.

In Fig. 2, the spin wave frequencies are shown as a function of ϕ_H with an applied field of 3.0 kOe which is sufficient to yield saturation in the hard direction at $\phi_H = 90^\circ$. The appearance of the crystalline anisotropy is evident in the structure of the data near 90° . The best fit to Figs. 1 and 2 (solid dots) obtained with simultaneous adjustment of parameters K_1 , K_p , K_u , g , and A gave $K_1 = -4.5 \times 10^5 \text{ ergs/cm}^3$ while the value for the uniaxial anisotropy K_u is $9.0 \times 10^5 \text{ ergs/cm}^3$. A negative K_1 places its easy axes along $[111]$. For

FIG. 2. In-plane angular dependence ϕ_H of the surface and two lowest bulk spin waves. The applied magnetic field is 3.0 kOe and the angle of incidence is 30° . The dotted lines are fits to the data using $K_1 = -4.5 \times 10^5 \text{ ergs/cm}^3$, $K_u = 9.0 \times 10^5 \text{ ergs/cm}^3$, $K_p = -22 \times 10^5 \text{ ergs/cm}^3$, $g = 2.1$, and $A = 1.4 \times 10^{-6} \text{ ergs/cm}$.

the (110) surface, a $[111]$ direction is at $\phi_H = 55^\circ$. Since K_1 is a fourth-order anisotropy, M_s would prefer to stay near the $[111]$ direction even for ϕ_H fairly far from 55° . This leads to the sharp narrow dip at $\phi_H = 90^\circ$ as M_s finally moves closer toward the field direction when H_0 is within about 15° of the $[110]$ axis. With these two anisotropy constants (K_1, K_u), the calculated saturation field $2(K_u - K_1)/M_s$ is 2.37 kOe, which agrees well with the dip in Fig. 1 and hysteresis measurements.¹ Once A , K_1 , and K_u were determined, we found that $K_p = -22 \times 10^5 \text{ ergs/cm}^3$ gave good agreement for all experiments.

Inspection of Figs. 1 and 2 show that there is good agreement between the frequency data and theory using the values for the anisotropies and exchange given above. The values determined for the uniaxial anisotropies are consistent with those measured in thinner bcc Co films and with estimates based on magnetoelastic effects.⁷ The fourfold K_1 anisotropy is roughly twice that found in a 216 \AA (100) film.⁷ A fourfold anisotropy is consistent with the cubic symmetry of the bcc crystal and may therefore be magnetocrystalline in origin.

A problem however appears when we examine the measured light scattering intensities. Intensities for the magnons vs ϕ_H measurements are shown in Fig. 3. The strongest intensity peaks are labeled by S and are normally due to scattering from surface magnons. Therefore the peak B_1 is assigned to the lowest order bulk mode. Note that frequencies of S and B_1 peaks are very close for this film thickness, which means that hybridization between them may be significant.

The problem mentioned above is that based on the observed intensities modes S and B_1 appear to cross between

FIG. 3. Brillouin spectra showing the in-plane angular (ϕ_H) dependence at a fixed field of 3.0 kOe. The strong features are labeled as "S" for surface spin wave and the weak features as "B1" for the lowest order bulk mode. The incident power was about 100 mW with total accumulation time per spectrum of about 1 h.

$\phi_H=50^\circ$ and $\phi_H=80^\circ$ in Fig. 3. A possible mode crossing is also suggested by experimental data in Fig. 1 at 1.9 kOe. However the calculated mode profiles using the parameters determined above do not show such a crossing.¹³ Instead the mode profile calculations predict that the surface mode remains the lowest frequency peak for all ϕ_H as shown by the fits in Fig. 2. If mode crossing is present, then a gap (small but not significantly smaller than 2 GHz) in the frequencies as the modes cross should exist.¹⁴ In addition if there is crossing, from the data in Fig. 2, it would follow that the surface mode must be less strongly influenced by the anisotropies than the bulk modes. This could happen when surface anisotropies are introduced to "pin" the bulk modes.¹³ However, including a single simple surface anisotropy still could not reproduce the mode behavior shown in Fig. 2 since the data require that the repulsion take place over a large range of orientation angles $50^\circ \leq \phi_H \leq 80^\circ$. The surface anisotropy represents differences between effective internal fields at the very surface and the bulk fields; a distribution of surface anisotropies would be required to pro-

duce a repulsion similar to that suggested by the data. This would mean the existence of a distribution of inhomogeneities in the internal effective magnetic fields that may extend over several atomic layers near the film surface. Evidence for variation of M_s with depth has, in fact, been reported in a thin bcc Co film grown on GaAs.¹⁵ It is noted however that in this particular bcc Co film where S and B_1 are strongly hybridized it is important that, in addition to the mode profiles considered here, the scattering cross sections of the spin waves be considered in making the assignment of the magnon peaks. This is underway and will be published elsewhere.¹³

In summary, we have examined in detail the magnetic anisotropies of a 357-Å-thick bcc Co film using Brillouin light scattering. An in-plane uniaxial anisotropies (K_u) with the easy axis along the [001] direction and an out-of-plane uniaxial anisotropy (K_p) were found with magnitudes and signs in agreement with those of thinner bcc Co films. An additional fourfold anisotropy (K_1) was determined by measuring spin wave frequencies with H_0 noncollinear with M_s . This anisotropy was much larger than that measured in thinner bcc Co films. Finally, examination of the spin wave frequencies and measured relative light scattering intensities suggest the existence of surface anisotropies and/or nonuniform internal fields.

Two magnon ferromagnetic resonance linewidths in uniaxial and planar single crystal hexagonal ferrites (abstract)

D. R. Franklin, M. J. Hurben, and C. E. Patton

Department of Physics, Colorado State University, Fort Collins, Colorado 80523

Hexagonal ferrites are ideally suited for millimeter-wave applications but have seen limited use because of large losses. High field effective linewidth and ferromagnetic resonance (FMR) linewidth measurements for single crystal barium ferrite indicate that these losses may be due to an inhomogeneity related two magnon scattering contribution to the relaxation.¹ Calculations of the linewidth as a function of the external magnetic field orientation in films and thin disks give characteristic dependencies if two magnon scattering relaxation is present.² The objective of this work was to measure the angle dependence of the FMR linewidth in single crystal Zn-Y and Ba-M hexagonal ferrite disks and compare the results to the theoretical predictions. The materials were flux grown Mn doped Ba-M and Zn-Y single crystals. The Ba-M and Zn-Y disks were 1.0 mm in diameter and 0.13 and 0.4 mm thick, respectively. Measurements were made at 53 GHz for the Ba-M and 9.5 GHz for the Zn₂-Y. The FMR was measured by a shorted waveguide technique as a function of the field angle relative to the out-of-plane direction. The linewidth for the Ba-M increased from minimum value of 35 Oe at 0°, to a maximum of 330 Oe at 68°, followed by a small decrease out to the maximum angle of 75° for which FMR could be observed. For the Zn₂-Y, the linewidth increased from 95 Oe at 0° to 420 Oe at 5°, followed by a decrease to 37 Oe at 90°. The two-magnon model gives large peaks in the linewidth as a function of angle, the sizes and positions of which depend upon the anisotropy and the size of the scattering inhomogeneities. The experimental results for both materials are in good agreement with model two-magnon calculations based on an inhomogeneity size on the order of 0.5 μm .

Quasi-one-dimensional magnetic materials provide important test beds for rigorous models of interacting many-body systems. Nevertheless, there have been few studies of finite temperature effects on spin correlations in low-spin systems, though these are most likely to exhibit quantum effects. Copper benzoate, $\text{Cu}(\text{C}_6\text{D}_5\text{COO})_2 \cdot 3\text{D}_2\text{O}$, is a good realization of the $S=1/2$ Heisenberg antiferromagnetic chain (HAFC).¹ We have performed ac susceptibility and inelastic neutron scattering experiments on this material which establish the Hamiltonian and an excitation spectrum which is consistent with the spinon continuum ansatz of Müller *et al.* We present inelastic neutron scattering measurements of the temperature evolution of the dynamic spin-spin correlation function $S^{zz}(\pi, \omega)$. Comparison will be made to the classical prediction and to a finite temperature field theory of Schulz as applied to this $S=1/2$ HAFC.² © 1996 American Institute of Physics. [S0021-8979(96)69008-8]

Cu₂(1,4-diazacycloheptane)₂Cl₄: A quasi-one-dimensional S=1/2 spin liquid system

Philip R. Hammar and Daniel H. Reich

Department of Physics and Astronomy, The Johns Hopkins University, Baltimore, Maryland 21218

The structure of Cu₂(1,4-diazacycloheptane)₂Cl₄ consists of well-separated zig-zag chains of Cu atoms, suggesting the possibility of significant antiferromagnetic near-neighbor and next-nearest-neighbor interactions. We report on measurements of magnetic susceptibility $\chi(H, T)$ and heat capacity $C_p(T)$ that show that this material does not behave as a simple linear antiferromagnetic chain with spin $S=1/2$. $\chi(H=0, T)$ shows a broad peak at 8 K indicative of one-dimensional antiferromagnetic correlations, but below the peak, χ drops dramatically toward zero instead of remaining finite as $T \rightarrow 0$. For $T \ll T_{\text{peak}}$, $\chi(H)$ is independent of field below a critical field $H_c \approx 6.6$ T, and rises sharply above H_c to a plateau at 8 T. Below T_{peak} , $C_p(T) \propto \exp(-\Delta/T)$ with an activation energy $\Delta = 6.8$ K. These data indicate the presence of a gap between the ground state and the lowest-lying excited states. This material is thus a candidate for a model quasi-one-dimensional $S=1/2$ system with a disordered ground state that is significantly affected by competing interactions. © 1996 American Institute of Physics. [S0021-8979(96)73008-1]

I. INTRODUCTION

The simplest way to introduce geometrical frustration in a one-dimensional (1D) antiferromagnet (AFM) is to include next-nearest-neighbor (NNN) interactions, as in the model Hamiltonian

$$\mathcal{H}_1 = J_1 \sum_i \mathbf{S}_i \cdot \mathbf{S}_{i+1} + J_2 \sum_i \mathbf{S}_i \cdot \mathbf{S}_{i+2}. \quad (1)$$

A potential physical realization of \mathcal{H}_1 is the zig-zag chain shown in Fig. 1(a), where the inside bonds are between near neighbors, and the outside ones between next-near neighbors. This model has received considerable theoretical attention, largely because for the particular value $J_2/J_1 = 1/2$ the ground state is known exactly.¹ At this point, there is a gap to excitations, and the two-spin correlation function is extremely short ranged,² both signatures of a spin liquid ground state. Despite these unusual features, however, there has been very little experimental work on NNN chain systems, due principally to the lack of good model systems. One of the only candidate materials known is Cu₂(1,4-diazacycloheptane)₂Cl₄ (CHpC). It was first synthesized by Chiari *et al.*³ who, based on its structure and high temperature susceptibility measurements, suggested that NNN interactions may be important in determining its behavior. In this article, we present a detailed exploration of the low-temperature magnetic and thermal properties of CHpC. Our results demonstrate the presence of a collective singlet ground state with a gap to magnetic excitations, and provide strong evidence that NNN interactions play a significant role in this material.

II. DATA

In the crystal structure of CHpC, the Cu₂(1,4-diazacycloheptane)₂Cl₄ molecules stack in a canted fashion, forming chains as sketched in Fig. 1(b).³ Small crystals may be grown by slow cooling of saturated methanol solutions. We produced clean powder samples for susceptibility and heat capacity measurements by grinding up such crystals. The dc susceptibility and magnetization for $T > 2$ K and mag-

netic fields $H \leq 5$ T were measured in a commercial (Quantum Design) superconductor, quantum interference device magnetometer. For $0.1 \leq T \leq 8$ K, and in dc fields up to 9 T, the ac susceptibility was measured with a home-built susceptibility meter mounted in a dilution refrigerator. Zero-field heat capacity measurements were also made in the dilution refrigerator using the relaxation method.⁴

Figure 2 shows the dc susceptibility $\chi_{\text{dc}} = M/H$ for CHpC, measured in an applied field $H = 20$ G. The characteristic rounded peak of a 1D AFM appears at $T_p = 8$ K. Fitting a Curie-Weiss law to the high temperature tail ($T > 30$ K) gives a Curie-Weiss temperature $\Theta_{\text{CW}} = -6.05(1)$ K, confirming the antiferromagnetic nature of the interactions. Below the peak, however, χ drops much more rapidly than for the linear $S=1/2$ chain with only NN interactions.⁵ The field dependence of the dc response M/H is shown in the inset of Fig. 2 at fields of $H = 0.1$ and 5.0 T. These data are largely field independent for $T > T_p$, but significant field dependence develops for $T < T_p$.

The field dependence of the ac susceptibility χ is shown in Fig. 3. At $T = 0.2$ K, $\chi(H)$ is essentially zero for $H < 4$ T. Between 5 and 7.5 T, however, $\chi(H)$ grows dramatically before saturating at a constant, nonzero value at high field. The fact that $\chi(H)$ remains zero over a large range of fields is an explicit demonstration that CHpC has a nonmagnetiz-

FIG. 1. (a) The ideal next-near-neighbor chain. The inner bonds (J_1) couple near neighbors, and the outer bonds (J_2) couple next-near neighbors. (b) Schematic of the chain structure of CHpC, indicating possible near-neighbor bond alternation (J_3). The ellipses show how the dimer units stack.

able, singlet ground state with a gap that prevents the excitation of spin-carrying excitations at low T . The gap is closed when the Zeeman splitting of these higher levels drives states with nonzero spin below the low-field ground state level. This leads to an increase in both χ and M . $M(H)$, as determined by integrating χ , is shown in the inset to Fig. 3. It is essentially zero up to a critical field H_c and rises linearly at high field. A linear extrapolation to $M=0$ yields $H_c=6.6(1)$ T. Figure 3 also shows the evolution of $\chi(H)$ with T . At $T=1.7$ K the gap is still well developed at low field, but thermal excitations cause χ to increase before H reaches H_c . At $T=3$ K and $T=6$ K, there are significant thermal excitations above the gap even at low field, and the field dependence for the higher temperatures shown in Fig. 2 is recovered.

Additional evidence for a gap can be found in the specific heat, C_p , of CHpC shown in Fig. 4. The lattice component of C_p (the solid line in Fig. 4) was determined by fitting the data for $T>10$ K to $C_p=AT^{-2}+BT^3$ to extract the phonon piece from the Shottky-like tail of the magnetic peak.⁶ The magnetic contribution to C_p appears as a bump super-

imposed on the phonon contribution. Below the maximum in the magnetic contribution, C_p is activated, as can be seen in the inset to Fig. 4, which shows $\ln C_p$ vs $1/T$. The excellent linear fit shown indicates that $C_p \propto \exp(-\Delta/T)$, with $\Delta=6.8(2)$ K.

III. DISCUSSION

In their pioneering work on CHpC,³ Chiari *et al.* pointed out that this material may differ from the Hamiltonian \mathcal{H}_1 through the presence of more than two Cu-Cu exchange couplings. On the basis of high temperature susceptibility data alone, they were not able to place strong constraints on the possible models, but they concluded that the most likely situation is that the intradimer and interdimer NN interactions are different as indicated in Fig. 1(b). In a material where there are several exchange constants present, it is difficult to determine them individually from bulk measurements. One is therefore forced to consider a variety of possible models to determine which best describes the system at hand.

The simplest system with a singlet ground state and a gap consists of isolated dimers with an AFM intradimer interaction. At high temperatures $\chi(T)$ in this model is described by a Curie-Weiss law with $\Theta_{CW}=-S(S+1)J/3$, where J is the strength of the intradimer exchange. With $S=1/2$ and $\Theta_{CW}=-6.05$ K, this implies $J=24.2$ K. The heat capacity in this model, however, shows activated behavior with $\Delta=J$. This is inconsistent with our measured value $\Delta=6.8$ K.

We note that the linear rise of $M(H)$ at low temperatures and high fields rules out not only the dimer model, but any collection of isolated groups of spins with a spectrum of discrete levels. $M(H)$ in such a system at low T will have a set of steps as a series of discrete levels with increasing spin successively becoming the ground state with increasing field. A linear $M(H)$ response can only arise if there is a band of finite-spin excitations above the gap that is continuously populated for $H>H_c$. Such behavior is well documented in the case of the Haldane gap in $S=1$ AFM chains.⁷ This fea-

ture of our data suggests that the ground state is cooperative in this material, and the excitations are extended.

We now consider several possible extended linear chain models. The uniform near-neighbor chain is easily ruled out by the presence of the gap, as discussed above. Alternation of the near-neighbor interaction

$$\mathcal{H}_2 = \sum_{i=1}^{N/2} [J_1 \mathbf{S}_{2i} \cdot \mathbf{S}_{2i+1} + J_3 \mathbf{S}_{2i+1} \cdot \mathbf{S}_{2i+2}] \quad (2)$$

introduces a gap between the singlet ground state and the lowest $S=1$ excited state.¹⁸ This model could be appropriate for CHpC if the NNN coupling were very weak [$J_2=0$, $J_1 \neq J_3$ in Fig. 1(b)]. Hatfield has described a method for fitting $\chi(T)$ in this model to determine J_1 and J_3 .⁹ In this method, χ is fit by the ratio of a quadratic and a cubic equation in J_1/T whose coefficients are polynomials of the ratio $\alpha=J_3/J_1$, found by fitting to exact diagonalization solutions to the alternating chain Hamiltonian of 10 spins. For the alternating chain, one expects $\Theta_{CW} = -S(S+1)(J_1+J_3)/3 = S(S+1)J_1(1+\alpha)/3$, which for our results implies $J_1=24.18/(1+\alpha)$ K. Fitting $\chi(T)$ using Hatfield's prescription with the addition of this constraint gives $\alpha=0.58(1)$ and thus $J_1=15.3(1)$ K. This fit is shown as a solid in Fig. 2. From numerical work on this model,¹⁰ we find that for $\alpha=0.58$, $\Delta=0.34(1) J_1$. This gives $\Delta=5.2(1)$ K, which is inconsistent with the value of 6.8 K determined from our $C_p(T)$ data. Thus the simple alternating chain also fails to describe adequately this material.

The final model that we consider is the NNN chain without alternation, given by Eq. (1). We have calculated $\chi(T)$ for a range of J_2/J_1 from exact diagonalization of chains of up to 14 spins. Based on finite-size scaling, we expect this calculation to be accurate to 1% for $T>0.21J_1$. The best fit

is obtained for $J_2/J_1=0.30(1)$, but as shown by the dashed line in Fig. 2, it is not satisfactory, and it is therefore unlikely that this model is sufficient.

Having exhausted these simpler possibilities, we are forced to the conclusion that at least three different exchange constants are important in this system, and that bond alternation as well as competing NNN interactions are necessary to describe the behavior of this material. We note that we have found no evidence for three-dimensional ordering down to $T=0.2$ K in either the susceptibility or the heat capacity, and thus the singlet ground state of the 1D system appears to be robust, a rarity for $S=1/2$. Despite its complexity, therefore, CHpC is deserving of further exploration as a model 1D system with competing interactions.

Raman spectra of the magnetic fluctuation spectrum of CuGeO_3 are presented for $4 < T < 300$ K and $B \leq 20$ T. For $B=0$ the results show good agreement with theoretical expectations for a one-dimensional isotropic Heisenberg antiferromagnet which exhibits a spin-Peierls transition. In the presence of a magnetic field the phase transition to the incommensurately modulated phase is observed around $B=12.8$ T at $T=4.2$ K. The spectra obtained in the high field phase clearly show evidence for a well-defined spin fluctuation spectrum, which appears to present an intermediate case between the dimerized phase and the short-range order regime of the uniform phase. © 1996 American Institute of Physics. [S0021-8979(96)73108-8]

I. INTRODUCTION

Recently it has been shown that CuGeO_3 , an inorganic compound, undergoes a spin-Peierls distortion below 14 K.¹ The magnetic interactions above this second-order transition are well described as a nearly one-dimensional isotropic $S=1/2$ Heisenberg antiferromagnet. The magnetic fluctuations in such a quantum system are of special interest due to the lack of long-range order, and differ substantially from what one expects for a classical system. In the dimerized (D) phase, one expects a gap in the fluctuation spectrum. The occurrence of this gap in CuGeO_3 has been confirmed by various experimental techniques.²⁻⁴ Applying a magnetic field in the D phase induces a second phase transition, of first order, to a presumably incommensurate (IC) phase around $B=13$ T.^{3,5}

CuGeO_3 has an orthorhombic structure with a space group $Pbmm$.⁶ The magnetic chains are formed by the $S=1/2$ Cu^{2+} ions running along the c axis of the crystal. The magnetic interaction is described by the isotropic Heisenberg Hamiltonian $H = \sum_i 2J_i \mathbf{S}_i \cdot \mathbf{S}_{i+1}$, with an intrachain exchange coupling $J = J_c \approx 60$ K. In the dimerized phase small interchain couplings $J_b \approx 0.1J_c$ and $J_a \approx -0.01J_c$ have been found.²

The present article is concerned with the magnetic fluctuation spectrum of CuGeO_3 in the uniform (U), the D, and the IC phase as probed by polarized Raman scattering experiments. Generally the most important contribution to magnetic inelastic scattering in antiferromagnets is the exchange scattering mechanism. In CuGeO_3 the scattered intensity can be expressed as $I(\omega) \propto \sum_{\mathbf{q}} f_{\mathbf{q}} \langle S_{\mathbf{q}}^{\alpha}(t) S_{-\mathbf{q}}^{\alpha}(t) \times S_{\mathbf{q}}^{\alpha}(0) S_{-\mathbf{q}}^{\alpha}(0) \rangle_{\omega}$, where $f_{\mathbf{q}} = \cos^2(q_c)$ is the weighing function which arises from the matrix elements for the exchange interaction.⁷ The magnetic scattering is thus mainly due to the density of states (DOS), and the structure therein, in the first-half of the Brillouin zone.

II. EXPERIMENT

The samples used in this study were grown from the melt by a floating zone technique.⁸ They were cleaved perpendicular to the (100) direction and mounted in a cold fin-

ger flow cryostat (temperature accuracy ~ 1 K). Raman spectra have been recorded in a backscattering geometry using a charge-coupled device equipped spectrometer (DILOR XY). The 514 nm line of an Ar-ion laser was used for excitation, keeping the intensity below 200 W/cm^2 to minimize local heating. Polarized experiments have been performed in a $(\mu\nu)$ scattering geometry, where μ, ν denote the polarization of the incident and scattered light, respectively. Magnetic scattering is only observed in the (cc) geometry, where c is along the chain direction. The results obtained in other geometries, as well as the results on vibrational scattering and wavelength dependence will be presented elsewhere.⁹

III. RESULTS FOR $B=0$ T

The magnetic scattering in CuGeO_3 is found to be strongly temperature dependent. As shown in Fig. 1, three types of behavior can be distinguished. In the uniform phase a well-defined broad scattering band is observed centered around 230 cm^{-1} for temperatures below 60 K [Fig. 1(b)]. This is also the temperature where the maximum in the susceptibility curve is observed. Above this temperature the scattered intensity is observed to be transferred to a quasi-elastic central peak which gains intensity as the temperature increases [Fig. 1(c)]. In the D phase [$T < 14$ K, Fig. 1(a)], the broad maximum becomes sharp, and several new, sharp features appear in the spectrum at 32, 105, 370, and 820 cm^{-1} .

A detailed discussion of the results obtained for $B=0$ has been given elsewhere.⁷ Here only the key points are discussed. The observed spectra in the U phase can be understood in terms of the magnetic fluctuation spectrum expected for a one-dimensional $S=1/2$ Heisenberg antiferromagnet.¹⁰ Although such a system does not order, not even at $T=0$, short-range correlations do develop at low temperatures. In this short-range order (SRO) regime the fluctuation spectrum is expected to form a continuum in (ω, \mathbf{q}) space, bounded by $\omega_1(q_c) = \pi J |\sin(q_c)|$ and $\omega_2(q_c) = 2\pi J |\sin(q_c/2)|$. The intensity of the fluctuations in this spin wave continuum (SWC) diverges at the lower limit $\omega_1(q_c)$, and rapidly decreases for increasing frequency. Using this description one can now understand the observed spectrum in the SRO regime [Fig. 1(b)]. The maximum in intensity around 230 cm^{-1} arises due

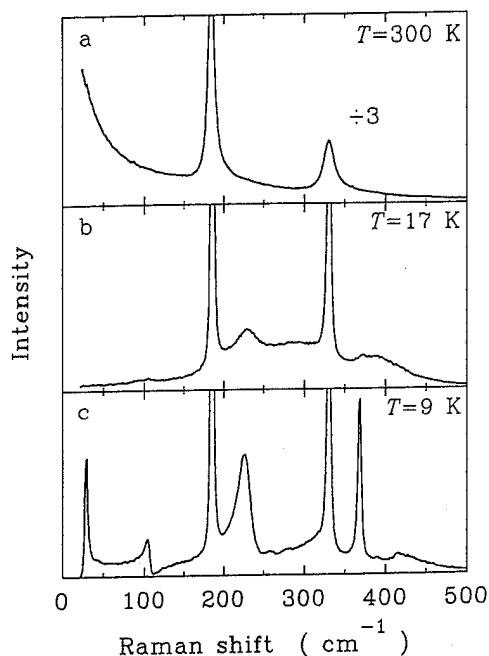

FIG. 1. Polarized (cc) Raman spectra of CuGeO_3 in the uniform and dimerized phases. (a) Uniform phase, high temperature regime. (b) Uniform phase, short-range order regime. (c) Dimerized phase. Spectrum (a) has been scaled down by a factor of 3.

to fluctuations around $q_c = \pi/2$, where the flatness of $\omega_1(q_c)$ yields a strongly peaked DOS. Model calculations including only the SWC show a good agreement with the observed spectrum for $\omega < 250 \text{ cm}^{-1}$, using $J = 60 \text{ K}$. The intensity at higher energies, however, cannot be due to the SWC. The origin of this high energy scattering is not fully understood at present, but preliminary results on the pressure dependence of the spectrum indicate that it is due to spin-phonon interactions.⁹

As the temperature increases the magnetic correlation length becomes shorter and the above picture breaks down. In the absence of correlations the magnetic fluctuations become diffusive, and the intensity of the fluctuation spectrum is transferred toward $(\omega, \mathbf{q}) = (0, 0)$. Since the magnetic system of CuGeO_3 is nearly one dimensional this leads to a divergent DOS at $\omega = 0$. The Raman spectrum at high temperatures [$T > 60 \text{ K}$, Fig. 1(a)] indeed shows a quasidiverging central peak with a tail extending up to 400 cm^{-1} .

The magnetic fluctuation spectrum in the D phase [Fig. 1(c)] shows two peaks which can be assigned to two-spin scattering processes. The first peak at 32 cm^{-1} is due to the spin-Peierls gap at $(q_b, q_c) = (0, \pi)$, and shifts to lower frequency as the temperature approaches the spin-Peierls transition. The peak around 230 cm^{-1} is due to the maximum in the DOS for $q_c = \pi/2$. In addition to this purely magnetic scattering there are several other peaks observed in the D phase, which disappear in the U phase. The asymmetric peak at 105 cm^{-1} could be due to the gap in the fluctuation spectrum at $(q_b, q_c) = (0, 0)$. However, the position of the peak is independent of temperature and no splitting of this peak has been observed in a magnetic field. Therefore this peak cannot be due to a spin-Peierls gap. It is more likely that this peak

FIG. 2. Unpolarized Raman spectra of CuGeO_3 in the D and IC phase at $T = 4.2 \text{ K}$. (a) D phase, $B = 1 \text{ T}$, (b) IC phase, $B = 20 \text{ T}$.

is in fact due to a phonon which is activated by the cell doubling in the D phase, where its asymmetry is due to a coupling to the spin system. Also the peak at 370 cm^{-1} cannot be due to purely magnetic excitations, given its relatively high energy, and again the cell doubling in the D phase may be responsible for the appearance of this peak in the Raman spectrum.

IV. RESULTS FOR $B \neq 0 \text{ T}$

Figure 2 shows representative unpolarized Raman spectra for the D phase ($B = 1 \text{ T}$) and the IC phase ($B = 20 \text{ T}$) at $T = 4.2 \text{ K}$. In order to clarify the magnetic contribution, the B_{1g} phonon at 228 cm^{-1} has been suppressed by subtracting the same Lorentzian peak from both spectra. It is interesting to compare the spectrum observed in the IC phase to those obtained in the D phase and in the SRO regime, since the spectrum observed in the IC phase appears to present an intermediate case between those in the D phase and in the SRO regime. It is clear that, like in the SRO regime, in the

FIG. 3. Field dependence of the 370 cm^{-1} mode showing the discontinuous decrease at the D-IC phase transition around 12.8 T . The mode at 394 cm^{-1} is assigned to a B_{1g} phonon.

IC phase the maximum around 230 cm^{-1} broadens and loses some intensity as compared to the D phase, but the changes are found to be less drastic. Also the increase in intensity for energies above 230 cm^{-1} found in the SRO regime is observed in the IC phase, but again is less pronounced. Hence, many of the characteristics of the D phase are retained in the IC phase. This also holds for the mode observed at 370 cm^{-1} in the D phase, which is absent in the SRO regime. In fact the intensity of this mode provides a convenient means to study the phase transitions in CuGeO_3 . Upon increasing the temperature from either the IC or the D phase the intensity of this mode continuously decreases until it has completely disappeared at the second-order phase transition to the U phase. The magnetic field dependence at 4.2 K of this mode is shown in Fig. 3, which also shows the B_{1g} phonon at 390 cm^{-1} . This phonon structure is found to be field independent, and is used as a reference for comparison to the 370 cm^{-1} feature. Upon increasing magnetic field, starting from the D phase the intensity of the 370 cm^{-1} mode slowly decreases. At the first-order D-IC phase transition the intensity drops sharply by about 20% over 0.2 T, after which it continues to decrease slowly until it reaches a more or less stable value around 17 T. Clearly this mode is intrinsic not only to the D phase, but also to the IC phase.

The observation that the Raman spectra in the IC phase shows characteristics of both the D phase and the SRO regime might not be so surprising since one can anticipate that the *average* structure of the high field phase is the same as the structure of the U phase, whereas the *actual* structure is likely to be close to the dimerized structure of the D phase. In other words, it seems likely that the D phase is the lock-in phase of the IC phase, which itself is obtained by an incommensurate modulation of the U phase with a modulation wave vector close to $1/2$ (the commensurate modulation of the D phase). Whether this picture holds, however, remains to be proven and has to await theoretical results for the IC phase which are not available at present.

V. CONCLUSIONS

The results obtained on the fluctuation spectrum of CuGeO_3 in the U phase clearly show the importance of quantum spin fluctuations in this system. In the first place the observed maximum around 230 cm^{-1} can only be understood from a quantum description, classically this energy is scaled down by a factor $\pi/2$. In the second place, the spectrum in the SRO regime of the U phase has no classical interpretation and is due to SWC excitations. In the third place the observed diffusive scattering at low energies which start to develop already at low temperatures, and dominates the high temperature spectra is in good agreement with the $T > 0$ finite quantum spin chain calculations of Müller *et al.*¹⁰

The results obtained in the IC phase clearly show the existence of a continuum of spin excitations, whose spectrum appears to present an intermediate spectrum between the D phase and the SRO regime of the U phase.

It is clear from the discussions in the present article that many aspects of the spin fluctuation spectrum are only qualitatively understood. This is mainly due to the lack of theoretical results for B and/or $T \neq 0$ for this magnetoelastic compound. We hope therefore that the present results stimulate further theoretical and experimental work on this fascinating system.

We have performed high-resolution neutron powder diffraction measurements on CeMn_2Si_2 and CeMn_2Ge_2 at temperatures between 12 and 550 K. Our measurements indicate that at high temperatures both compounds are paramagnetic. Below $T_N=380$ K CeMn_2Si_2 becomes a collinear AF, with a structure similar to that reported by Siek *et al.* in which the magnetic propagation vector is $\tau=(0\ 0\ 1)$. CeMn_2Ge_2 , on the other hand, exhibits two different magnetic transitions. At $T_N\approx 415$ K there is a transition to a collinear AF phase characterized by the commensurate propagation wave vector $\tau=(1\ 0\ 1)$. At $T_C\approx 318$ K there is a transition to a conical structure with a ferromagnetic component along the c axis and a helical component in the ab plane. The helical component is characterized by the incommensurate propagation vector $\tau=(1\ 0\ 1-q_z)$, where q_z is temperature dependent. © 1996 American Institute of Physics. INTRODUCTION

The family of layered compounds of the form RM_2X_2 (R =rare earth, M =transition metal, X =Si, Ge) crystallizes with the ThCr_2Si_2 ($I4/mmm$) structure and exhibits a rich variety of interesting physical phenomena that include superconductivity, magnetism, mixed valence, heavy fermion or Kondo behavior. Of particular interest is the system CeMn_2X_2 , which exhibits magnetic moments only at the Mn sites. In this system the Mn atoms form a simple tetragonal lattice and are coupled with an exchange interaction that has been thought to be sensitive to the Mn-Mn distances within $(0\ 0\ 1)$ planes (intralayer exchange) and relatively insensitive to the Mn-Mn distances along the c axis (interlayer exchange). It has been reported that the Mn moments in CeMn_2Si_2 are aligned ferromagnetically within the $(0\ 0\ 1)$ planes, and that these planes are coupled antiferromagnetically below $T_N=379$ K.¹ The CeMn_2Ge_2 system, on the other hand, has been reported to be ferromagnetic (FM) below $T_C=316$ K.^{2,3} Recently Venturini *et al.*⁴ have reported that in the related compounds LaMn_2Si_2 and LaMn_2Ge_2 there is strong evidence of dominant intralayer antiferromagnetic interactions, which give rise to conical incommensurate phases at low temperatures. These results suggest that the nature of the magnetic interactions in this family of compounds is more complex than originally thought, and that the magnetic structures of CeMn_2Si_2 and CeMn_2Ge_2 should be reexamined. We have performed high-resolution neutron powder diffraction measurements on these compounds to resolve the magnetic structures and the nature of the magnetic interactions in these systems. In this article we report the findings of our preliminary analysis of these measurements. We found that at high temperatures both compounds are paramagnetic. CeMn_2Si_2 becomes a collinear antiferromagnet below $T_N\approx 380$ K, with a structure similar to that reported by Siek *et al.*,¹ in which the magnetic propagation

vector is $\tau=(0\ 0\ 1)$. Below $T_N\approx 415$ K CeMn_2Ge_2 is a collinear antiferromagnet with a commensurate propagation wave vector $\tau=(1\ 0\ 1)$. Below $T_C\approx 318$ K the Mn moments in this system exhibit a conical structure with a ferromagnetic component along the c axis and a helical component in the ab plane, similar to that of LaMn_2Ge_2 reported by Venturini *et al.*⁴ This helical component is characterized by the incommensurate propagation vector $\tau=(1\ 0\ 1-q_z)$, where q_z is temperature dependent and varies from 0 (at T_C) to 0.32 reciprocal lattice units (at $T=12$ K). These findings are consistent with the recent results reported by Welter *et al.*⁵

EXPERIMENT

About 10 g of CeMn_2Ge_2 and CeMn_2Si_2 were prepared by arc melting stoichiometric amounts of the constituents in an argon atmosphere. X-ray diffraction analysis showed that these specimens had no significant amounts of impurity phases. The samples were powdered and loaded in thin-walled aluminum or vanadium cells for the neutron diffraction measurements. For the measurements between 12 and 330 K the cells were sealed in a He gas environment, and then placed in a closed cycle He refrigerator. For the high temperature measurements ($330\text{ K}<T<550\text{ K}$) the cells were placed in a furnace. The neutron diffraction measurements were performed at the HB4 high-resolution powder diffractometer at the High Flux Isotope Reactor at Oak Ridge National Laboratory using neutron wavelengths of 1.417 and 2.222 Å.

CeMn_2Si_2

Powder diffraction patterns of CeMn_2Si_2 were collected between 12 and 430 K. At 430 K there was no evidence of any magnetic contribution to the diffraction pattern, and the crystal structure at this temperature was refined using the computer program RIETAN.⁶ The refined structural param-

FIG. 1. Partial neutron powder diffraction pattern for CeMn_2Si_2 at $T=410$ K and 12 K. The low temperature (1 1 1) peak is of magnetic origin and is indicative of an antiferromagnetic structure with a characteristic propagation wavevector $\tau=(0\ 0\ 1)$ (see text). The solid lines are the result of fits to Gaussian lineshapes. The peak labeled with a question mark corresponds to an unidentified impurity phase. The neutron wavelength for this measurement was $\lambda=2.22$ Å.

eters are consistent with the published values for this material with the Ce, Mn, and Si atoms at the 2(a), 4(d) and 4(e) sites of the space group $I4/mmm$, $a=4.0417(6)$ Å, $c=10.5546(19)$ Å, and $z=0.382(1)$ (where z is the variable fractional coordinate of the Si atoms). In this space group the nuclear reflection conditions for (hkl) are $h+k+l=2n$. An extra reflection condition, $l=2n$, exists for the scattering contribution from the Mn sites. As the temperature was lowered two superlattice peaks were observed. These could be indexed as the (1 1 1) (see Fig. 1) and the (1 1 3) reflections. These superlattice peaks appeared below $T_N \approx 380$ K and persisted all the way down to 12 K. These findings are similar to those reported by Siek *et al.*¹ and correspond to an antiferromagnetic structure with a propagation vector $\tau=(0\ 0\ 1)$. The absence of reflections of the form $(0\ 0\ 2n \pm 1)$ indicates that the magnetic moments are parallel to the c axis. In this collinear antiferromagnetic structure the magnetic moment M_z at the Mn site \mathbf{r}_1 is

$$M_z(\mathbf{r}_1) = M_0 \cos(\mathbf{r}_1 \cdot \boldsymbol{\tau}), \quad (1)$$

where $\boldsymbol{\tau}$ is the propagation vector characteristic of the magnetic structure in reciprocal lattice units, and M_0 is the magnitude of the magnetic moment. Thus in this structure all the Mn moments in the (0 0 1) planes are coupled ferromagnetically, while the moments in adjacent (0 0 1) planes are coupled antiferromagnetically. The magnetic moment per Mn atom at 12 K was calculated from the integrated intensities of the (1 1 1) magnetic peak and the (1 1 0) nuclear peak shown in Fig. 1. In this calculation a small correction (<5%) was made to account for the preferred orientation present in the powder. The calculated moment was of 1.9(2)

FIG. 2. Partial neutron powder diffraction pattern for CeMn_2Ge_2 at $T=521$ K and 12 K. The low temperature magnetic satellites in the vicinity of the (1 0 1) peak are of magnetic origin and are indicative of a helical component of the Mn magnetic moments with characteristic propagation wavevector $\tau=(1\ 0\ 1-q_z)$. The neutron wavelength for this measurement was $\lambda=2.22$ Å.

μ_B per Mn atom. This value is lower than the value 2.30(5) μ_B reported by Siek *et al.*¹ and lower than the paramagnetic moment of 3.3 μ_B reported by Liang *et al.*⁷ At $T=12$ K the refined structural parameters were $a=3.9913(4)$ Å, $c=10.4935(13)$ Å, and $z=0.3805(8)$.

CeMn_2Ge_2

Powder diffraction patterns of CeMn_2Ge_2 were collected between 12 and 550 K. At 550 K there was no evidence of any magnetic contribution to the diffraction pattern, and the crystal structure at this temperature was refined using the computer program RIETAN.⁶ This structure is similar to that of CeMn_2Si_2 , with the Ce, Mn, and Ge atoms at the 2(a), 4(d) and 4(e) sites of the space group $I4/mmm$, the refined structural parameter at 521 K were $a=4.1623(3)$ Å, $c=11.0081(9)$ Å, and $z=0.3832(5)$ (where z is the variable fractional coordinate of the Ge atoms). As the temperature was lowered we found evidence of two magnetic transitions. Below $T_N \approx 415$ K the intensity of the (1 0 1) reflection increased, reaching a maximum at about $T=320$ K and then dropped rapidly to the same level of the high temperature patterns. Below $T_C \approx 318$ K magnetic satellites appeared in the vicinity of the (1 0 1) (see Fig. 2), (1 0 3), (1 0 5), (2 1 1), and (2 1 3) reflections, at the same time that the intensity of the (1 1 0), (1 1 2), (1 1 4) and (2 0 2) peaks increased. The intensities of the reflections $(0\ 0\ 2n)$ remained unchanged in the whole temperature range studied. These observations are consistent with the existence of two different magnetic phases in CeMn_2Ge_2 .

The enhancement of the (1 0 1) reflection below T_N could originate either by the appearance of ferromagnetic

FIG. 3. Temperature dependence of q_z for CeMn_2Ge_2 . q_z is given in reciprocal lattice units (r.l.u.).

ordering of the Ce atoms, or by the appearance of antiferromagnetic ordering of the Mn atoms (i.e., by the formation of a superlattice of Mn atoms). The magnetic ordering of the Ce atoms, however, would also increase the intensity of most of the allowed nuclear reflections. This intensity enhancement has not been observed, indicating that no magnetic ordering is associated with the Ce atoms. This observation is consistent with earlier reports that Ce is nonmagnetic in this family of compounds.^{8,9} Other Lanthanides in RMn_2X_2 systems exhibit magnetic order but at much lower temperatures.⁸ The enhancement of the (1 0 1) reflection can then be attributed to the antiferromagnetic ordering of the Mn atoms with a characteristic propagation wave vector $\tau = (1\ 0\ 1)$. As in the case of CeMn_2Si_2 the direction of the magnetic moments is parallel to the c axis. Unlike the CeMn_2Si_2 system both the intralayer and interlayer couplings of the Mn moments are antiferromagnetic, their directions given by Eq. (1).

The enhancement of the (1 1 0), (1 1 2), (1 1 4) and (2 0 2) peaks below $T_c \approx 318$ K can be attributed to the development of a ferromagnetic alignment of the Mn moments. The appearance of magnetic satellites at the same temperature can be attributed to the simultaneous appearance of a helical component of the Mn moments in the ab plane, with a characteristic wave vector $\tau = (1\ 0\ 1 - q_z)$. The value of q_z is incommensurate with the lattice and is temperature dependent (see Fig. 3), varying from 0 (at T_c) to ≈ 0.32 (at 12 K). In this structure the M_x , M_y , and M_z components of the magnetic moment $\mathbf{M}(\mathbf{r}_1)$ are given by

$$\begin{aligned} M_x(\mathbf{r}_1) &= M_0 \cos(\mathbf{r}_1 \cdot \tau + \phi), \\ M_y(\mathbf{r}_1) &= M_0 \sin(\mathbf{r}_1 \cdot \tau + \phi), \quad M_z(\mathbf{r}_1) = M_1. \end{aligned} \quad (2)$$

These components result in a conical structure similar to that described by Venturini *et al.* for LaMn_2Ge_2 .⁴ The refined fer-

romagnetic component M_z for Mn at $T = 12$ K was $2.4(2)\mu_B$. The refined structural parameters at this temperature were $a = 4.1291(2)$ Å, $c = 10.9016(7)$ Å, and $z = 0.3820(4)$.

DISCUSSION

The nature of the magnetic interactions in the systems under study is more complex than originally thought. The short distance between the Mn nearest neighbors ($a\sqrt{2}/2$) is suggestive of strong direct exchange interactions between the magnetic ions. The relatively large distance ($c/2$) between the Mn (0 0 1) planes suggests indirect exchange interactions mediated by the Ge/Si and Ce atoms. For CeMn_2Si_2 the intralayer exchange interaction between Mn moments is ferromagnetic, while the interlayer is antiferromagnetic. For CeMn_2Ge_2 on the other hand, the intralayer exchange is antiferromagnetic, while the interlayer is such that gives rise to a transition from a commensurate antiferromagnetic phase to an incommensurate conical structure. The nature of this commensurate-to-incommensurate phase transition, which takes place with a magnetic moment reorientation is of special interest and should be studied further. Recent bulk magnetization measurements on a specimen of CeMn_2Ge_2 (from the same batch as our sample) revealed an anomaly in the magnetization at the same temperature where this spin reorientation takes place.¹⁰ When this work was in progress we learned of the recent published results of Welter *et al.*⁵ on CeMn_2Ge_2 ; our results on this system are in general agreement with theirs. Our results are also in general agreement with the recent Mössbauer experiments by Nowick *et al.*¹¹

Magnetic studies of the metal-insulator transition in $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ ($x=0, 0.1, \text{ and } 4$)

P. Somasundaram and J. M. Honig

Department of Chemistry, Purdue University, West Lafayette, Indiana 47907

T. M. Pekarek and B. C. Crooker

Department of Physics, Purdue University, West Lafayette, Indiana 47907

Magnetic properties and the metal-insulator transition in $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ with $x=0.0, 0.1$, and 4.0 were investigated. $\text{CuIr}_2\text{S}_{3.9}\text{Se}_{0.1}$ exhibits a transition from paramagnetism ($M/H=+1.3\times 10^{-7}$ emu/g G) at higher temperatures to diamagnetism ($M/H=-1.5\times 10^{-7}$ emu/g G) at lower temperatures and exhibits hysteresis on heating and cooling. The transition on warming in $\text{CuIr}_2\text{S}_{3.9}\text{Se}_{0.1}$ occurs at a lower temperature (200 K) than in CuIr_2S_4 (218 K) and is not observed in CuIr_2Se_4 . © 1996 American Institute of Physics. [S0021-8979(96)73308-0]

I. INTRODUCTION

Among the chalcogenide spinel compounds, CuRh_2S_4 exhibits superconductivity with a transition temperature of 4.7 K.¹⁻³ Recently a new thiospinel compound, CuIr_2S_4 , with the same structure was synthesized.⁴ This compound exhibits a metal-insulator transition with a transition temperature $T_i=230$ K. The resistivity increases by more than two orders of magnitude below T_i . This metal-insulator transition is also accompanied by a first-order structural transition from cubic spinel above T_i to tetragonal below as well as a paramagnetic to diamagnetic transition. We have investigated the effects of Se substitution in the $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ system using x-ray diffraction, conductivity, magnetization, and heat capacity measurements. The results of magnetic studies are presented below for samples with Se concentrations $x=0.0, 0.1$, and 4.0 .

II. EXPERIMENT

Stoichiometrically mixed powders of Cu, Ir, S, and Se were calcined at 850 °C in sealed quartz ampoules for 8 days. After regrinding, the powders were pelletized and sintered at 850 °C for 4 days. During sintering the ampoules were enclosed with additional powder of the same composition to minimize the escape of S and Se from the pellet. Powder x-ray diffraction was performed on a Siemens D500 diffractometer with Cu $K\alpha$ radiation. Sintered samples were used for magnetization studies using a Cryogenic Consultants Limited superconducting quantum interference device magnetometer. Magnetization data were taken at 5–324 K in fields up to 6 T.

III. RESULTS AND DISCUSSION

The x-ray diffraction results at 300 K confirmed that the $x=0.0, 0.1$, and 4.0 compositions of $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ were monophasic at the limit of detection. Magnetization versus temperature measurements in a 0.1 T field for the $x=0$ and 0.1 samples are shown in Figs. 1(a) and 1(b). For the $x=0$ sample there is a sharp increase in magnetization on heating above $T_i=218$ K, and a sharp decrease below $T_i=206$ K. Here the transition temperature is defined as the temperature corresponding to half the change in magnetization. Resistance measurements were done on the CuIr_2S_4 sample using

a four-probe technique. The variation of resistance as a function of temperature is given as an inset of Fig. 1(a). As can be seen, there is a sharp change in resistance of approximately two orders of magnitude at the metal-insulator transition. Our transition temperatures T_i differ from those reported by Takao *et al.*⁴ who reported a T_i for CuIr_2S_4 of 238 K on heating and 226 K on a cooling. A detailed study of the dependence of the transition temperatures on the sulfur/metal ratio has to be carried out to understand this discrepancy. From Fig. 1(b) it is clear that the transition for the $x=0.1$ sample is shifted to lower temperatures, i.e., 200 K on warming and 188 K on cooling. The magnetization is almost tem-

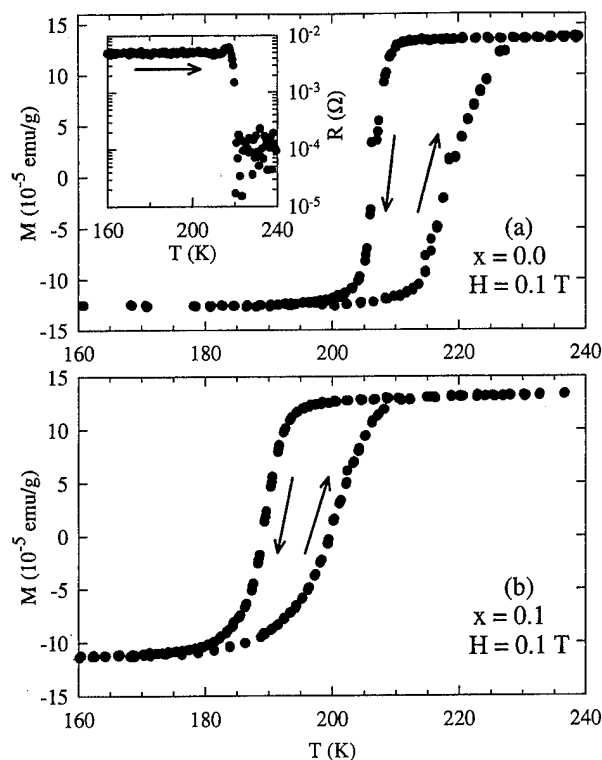

FIG. 1. Figures (a) and (b) show warming and cooling magnetization vs temperature data indicating a shift in the metal to insulator transition of $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ for $x=0.0$ and 0.1 , respectively. The inset of (a) shows resistance vs temperature data taken on warming in zero field.

FIG. 2. Magnetization vs temperature for CuIr_2Se_4 . The magnetization consists of a diamagnetic and a Curie contribution. No metal-insulator transition is present.

perature independent both above and below the transitions, suggesting a relatively constant carrier concentration at all temperatures in these regions. The magnetization is linearly proportional to the applied field at high (270 K) and low (150 K) temperatures. The values of M/H at 270 and 150 K for $\text{CuIr}_2\text{S}_{3.9}\text{Se}_{0.1}$ are $+1.3$ and -1.5×10^{-7} emu/g G, respectively. The change in magnetization at the metal-insulator transition is 2.7×10^{-4} emu/g for CuIr_2S_4 while for $\text{CuIr}_2\text{S}_{3.9}\text{Se}_{0.1}$ it is 2.5×10^{-4} emu/g. There is also a small Curie-like ($1/T$) variation at low temperature (< 50 K) which is likely due to the presence of residual iridium.

Unlike the previous two samples, the CuIr_2Se_4 sample does not exhibit a metal-insulator transition. As can be seen in Fig. 2 the magnetization is composed of diamagnetic and

Curie ($1/T$) terms. The variation of resistance as a function of temperature indicated that CuIr_2Se_4 is metallic from room temperature to 20 K.

Studies are underway to determine the variation of the metal-insulator transition temperature with Se concentration, x , and the point at which the metal-insulator transition disappears. Room temperature x-ray diffraction studies indicate that the spinel structure is maintained from $x=0.0$ to 4.0 in the $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ series even past the metal-insulator transition. Takao *et al.*,⁴ using magnetic susceptibility measurements, detected an increase in the metal-insulator transition temperature at higher pressures. This is contrary to the effect of pressure in most oxides that exhibit metal-insulator transition, including V_2O_3 , VO_2 , and Fe_3O_4 .^{5,6} Selenium substitution expands the lattice and reduces the chemical pressure, which should decrease the transition temperature of the metal-insulator transition, as observed in the present study.

IV. CONCLUSIONS

We have presented magnetic measurements on $\text{CuIr}_2\text{S}_{4-x}\text{Se}_x$ with $x=0.0$, 0.1, and 4.0. We found that the metal-insulator transition on warming in $\text{CuIr}_2\text{S}_{3.9}\text{Se}_{0.1}$ occurs at a lower temperature (200 K) than CuIr_2S_4 (218 K) and is not observed at all in CuIr_2Se_4 .

We have measured the temperature and magnetic field dependence of the magnetization for Gd_2In . The results show that Gd_2In exhibits a helical ferromagnetic transition at 190 K and an antiferromagnetic transition at 100 K in zero and low applied fields. Both the helical ferromagnetic state at temperatures between 100 and 190 K and the antiferromagnetic state at low temperatures are transformed to a simple ferromagnetic state by high applied fields. The antiferromagnetic transition temperature decreases with increasing applied field and approaches zero at $H=25$ kOe. We have also measured the temperature dependence of the specific heat for Gd_2In . The data show two distinct specific heat anomalies which are associated with the two magnetic transitions. © 1996 American Institute of Physics. [S0021-8979(96)73408-7]

Several rare-earth-based intermetallic compounds R_2In , where R =rare earths, undergo a magnetic phase transition below room temperature and exhibit magnetization that has an unusual temperature dependence at low temperatures.¹⁻⁵ Gamari-Seale *et al.*¹ and McAlister *et al.*⁶ have reported from measurements of the magnetization and electrical resistivity that Gd_2In orders ferromagnetically at $T_c=190$ K and orders as a metamagnetic antiferromagnet below $T_N=99.5$ K. McAlister *et al.* have also suggested that below 99.5 K Gd_2In has a spiral antiferromagnetic structure. However, Delyagin *et al.*⁷ have concluded from ^{119}Sn Mössbauer measurements for Gd_2In that the magnetic structure remains ferromagnetic over the entire temperature interval from 5 K to $T_c=190$ K. We have extended measurements of the temperature and magnetic field dependence of the magnetization in several respects. From measurements of the field dependence of the magnetization at several temperatures between 100 and 190 K, we infer that Gd_2In exhibits a helical ferromagnetic state between 100 and 190 K in both zero field and low applied fields. In high applied fields the helical ferromagnetic state is transformed to a simple ferromagnetic state. This behavior is similar to that previously observed from the magnetization measurements for MnSi ,⁸ $\text{Fe}_{1-x}\text{Co}_x\text{Si}$,⁹ and Co_2ScSn .¹⁰ The helical magnetic state of MnSi and $\text{Fe}_{1-x}\text{Co}_x\text{Si}$ has been confirmed by neutron diffraction studies.^{9,11} We have also measured the temperature and field dependence of the magnetization of Gd_2In below 100 K. The results show that Gd_2In is a metamagnetic antiferromagnetic at low temperatures and low applied fields. The antiferromagnetic state is induced to the ferromagnetic state by high applied fields, and T_N decreases monotonically with an increasing applied field approaching zero for a field of 25 kOe. In addition, we have measured the temperature dependence of the specific heat for Gd_2In and La_2In . To the best of our knowledge this is the first specific heat study for Gd_2In . The data for Gd_2In show two distinct specific heat anomalies at temperatures which are consistent with those obtained from magnetization measurements.

Polycrystalline Gd_2In and La_2In samples were prepared in an inert atmosphere arc furnace with appropriate care taken to compensate for the weight loss of the more volatile In. The samples were wrapped in Ta foils and were annealed under high vacuum at 800 °C for 7 days. Powder x-ray diffraction measurements at room temperature indicated that both the small magnetization sample (50 mg) and the larger specific heat sample (2 g) were single phase and crystallized with the Ni_2In structure. The lattice parameters $a=5.41$ Å and $c=6.76$ Å for Gd_2In are in good agreement with those previously published.¹² The magnetization was measured from 5 to 400 K in magnetic fields up to 5 T using a commercial superconducting quantum interference device magnetometer. The specific heat was measured from 15 to 300 K using a semiadiabatic heat pulse technique.

Shown in Fig. 1 is the temperature dependence of the magnetization of Gd_2In measured in applied fields of 200 Oe and 2 kOe. It can be seen from the data for $H=200$ Oe that the magnetization increases rapidly as the sample is cooled below 210 K and saturates at about 190 K, which is the magnetic phase transition temperature. The magnetization is essentially temperature independent from 190 down to 110 K. Below 110 K the magnetization decreases dramatically indicating a second magnetic transition. At lower temperatures the magnetization becomes temperature independent again. This behavior is the same as that previously reported by McAlister *et al.*⁶ The data measured at 2 kOe show a qualitatively similar behavior except that M decreases more gradually from 150 to 190 K and thus has a more "rounded" shape. Later we will show that the temperature independent behavior above 110 K completely disappears for higher fields. Shown in the inset of Fig. 1 is $1/M$ vs T measured at 2 kOe. It can be seen that the high temperature data, i.e., $T>240$ K, follow the Curie law. From the slope we can calculate the Curie constant and thus the paramagnetic effective moment. We find a value of $7.5 \mu_B$ which is reasonably close to the $7.94 \mu_B$ predicted theoretically for the trivalent Gd ion.¹³

FIG. 1. M vs T for Gd_2In measured at $H=200$ Oe and $H=2$ kOe.

In order to understand the temperature independent behavior of the magnetization between 110 and 190 K, we have measured the field dependence of the magnetization at several temperatures in this interval. Shown in Fig. 2 are the $M(H)$ curves measured at $T=110, 150, 170, 190$, and 200 K. Note that at $T=110$ K $M(H)$ increases linearly with increasing applied field up to a critical field H_c of about 2 kOe, then it starts to saturate when the applied field is increased further. This linear behavior of $M(H)$ at low fields is different from that of simple ferromagnets. For higher temperatures, e.g., $T=150, 170$, and 190 K, $M(H)$ shows the same type of behavior except the critical field H_c decreases. At $T=200$ K, the linear behavior disappears and $M(H)$ shows a negative curvature over the entire applied field range as one would expect for $T > T_{\text{Curie}}$. The $M(H)$ behavior described above has been observed for other magnets, e.g., MnSi ,⁸ $\text{Fe}_{1-x}\text{Co}_x\text{Si}$,⁹ and Co_2ScSn .¹⁰ This behavior has been explained in terms of a helical magnetic structure below T_c for zero and low applied fields. This interpretation has been con-

FIG. 2. M vs H for Gd_2In measured at $T=110, 150, 170, 190$, and 200 K.

FIG. 3. Arrott Plots (M^2 vs H/M) for Gd_2In at $T=150, 170, 190, 200$, and 210 K.

firmed by neutron diffraction and electron spin resonance measurements for the MnSi and $\text{Fe}_{1-x}\text{Co}_x\text{Si}$ systems.^{9,11} Moreover, theoretical calculations^{14,15} for helical magnets have predicted the same behavior. Mössbauer and spin resonance experiments to confirm the helical ferromagnetic structure of Gd_2In between 190 and 110 K would be useful.

To obtain the helical ferromagnetic transition temperature T_c , we have plotted M^2 vs H/M (Arrott plots) for Gd_2In at various temperatures. It can be seen from Fig. 3 that these plots do not show the linear behavior which is characteristic of simple ferromagnets. But these plots are similar to those obtained for the helical systems mentioned above. For simple ferromagnets the transition temperature is defined as the temperature for which a linearly extrapolated curve on the Arrott plot goes through the origin. However, for the helical systems T_c is obtained from low field M^2 vs H/M plots by selecting the isotherm for which the H/M axis intercept first deviates from the $T < T_c$ value. In Fig. 3 this is the $T=190$ K isotherm. This T_c value is the same as that determined by other groups^{6,16} from magnetization and electrical resistivity measurements.

It was mentioned earlier that the magnetization measured at $H=2$ kOe exhibits a rounded behavior for $T > 150$ K as shown in Fig. 1. This rounded behavior indicates that the helical ferromagnetic state is suppressed and a simple ferromagnetic state occurs for $T > 150$ K and $H=2$ kOe. It was also mentioned that the critical field H_c increases with decreasing temperature indicating that at lower temperatures, i.e., T near 110 K, the helical ferromagnetic state can only be suppressed by a much larger field. Shown in the main portion of Fig. 4 is the temperature dependence of the magnetization measured at higher fields, i.e., 10, 15, 20, and 25 kOe. It can be seen that the helical ferromagnetic state is completely suppressed and only a simple ferromagnetic state occurs for these fields.

Returning to Fig. 1, the temperature dependence of the low field magnetization shows that Gd_2In undergoes a second magnetic phase transition at a lower temperature. The

FIG. 4. M vs T for Gd_2In measured at $H=10, 15, 20$, and 25 kOe. Inset: M vs H for Gd_2In measured at $T=10$ K.

transition temperature which can be determined as the maximum slope of the magnetization has a value of 100 K for the data measured at 200 Oe. We have measured the field dependence of the magnetization at various temperatures below 100 K. Shown in the inset of Fig. 4 is $M(H)$ at $T=10$ K. For $H < 10$ kOe $M(H)$ increases linearly with increasing applied field. This linear field dependence together with the sharp decrease in magnetization with decreasing temperature in the vicinity of 100 K (see the data measured at $H=200$ Oe and 2 kOe shown in Fig. 1.) indicate that below 100 K Gd_2In has an antiferromagnetic state. The temperature independent magnetization below 100 K measured for low fields (e.g., 200 Oe shown in Fig. 1) could be due to a helical antiferromagnetic structure. McAlister *et al.*⁶ have proposed a spiral magnetic structure below 100 K by comparing the behavior of Gd_2In with that of other compounds.

The inset of Fig. 4 shows that for $H > 10$ kOe the magnetization measured at 10 K increases significantly (about a factor of 3) and finally saturates at the higher fields. This indicates that Gd_2In is a metamagnetic antiferromagnet at low temperatures and that the antiferromagnetic state is induced to the ferromagnetic state by high applied fields.

We have also measured the temperature dependence of the specific heat of Gd_2In and La_2In , which has not been reported in the literature. The results are shown in Fig. 5. It can be seen that two specific heat anomalies occur at 100 and 190 K for Gd_2In which are associated with the antiferromagnetic and helical ferromagnetic transitions, respectively.

To obtain the magnetic specific heat and calculate the entropy for Gd_2In , we need to subtract the phonon contribution from the total specific heat. However, the specific heat of La_2In cannot be used as the nonmagnetic specific heat contribution for Gd_2In since it is greater than the specific heat of Gd_2In below 50 K. In order to obtain the phonon contribution to the specific heat of Gd_2In , we have used the

FIG. 5. C vs T for Gd_2In and La_2In . The solid curve is the theoretical fit to the experimental data of Gd_2In . Inset: The magnetic specific heat of Gd_2In .

theoretical Debye model to fit the low temperature (below 50 K) and the high temperature (above 220 K) data of Gd_2In . Note that we have assumed that above 220 K the specific heat is only due to the phonon contribution. The fit is shown by the solid curve in Fig. 5. The magnetic specific heat can be extracted from subtracting the theoretical Debye curve from the total specific heat. The result is shown in the inset of Fig. 5. The magnetic entropy of Gd_2In below 200 K is estimated by the above procedure to be about 6 J/mol K. This value is much smaller than $2R[\ln(2J+1)] = 34$ J/mol K with $J=7/2$ for the disordered Gd moment. This small value could be due to the helical ferromagnetic state between 100 and 190 K and the helical antiferromagnetic state below 100 K.

We report on the simultaneous measurements of the magnetic viscosity and of the ac linear magnetic susceptibility for a sample of $\text{Cu}_{90}\text{Co}_{10}$. The magnetic viscosity $S = (1/M_0) [dM/d \ln(t)]$, with M the sample magnetization and M_0 the magnetization value at the beginning of the logarithmic relaxation, is measured by a standard method that involves the application to the sample of a large field step after saturation. The ac susceptibility is measured both directly at very low (\approx microersteds) ac field amplitudes and from the thermal magnetization noise in the sample, the two values always being found in quantitative agreement. The imaginary susceptibility is found to be a frequency independent value $\chi''_0(T)$ at low frequencies, a behavior that translates, when expressed in the time domain, to logarithmic relaxation $(dM/d \ln t) = (2/\pi)\chi''_0(T)H_0$, of the magnetization after a step excitation H_0 . Both S and $\chi''_0(T)$ are found to be proportional to the temperature for temperatures ≤ 4.2 K. In addition, S and $\chi''_0(T)$ are found to be of the same order of magnitude. We discuss how these results are in agreement with the idea that in both kinds of experiments one is probing an energy barrier height distribution and that, in addition, the size of the distribution involved in the "critical state," prepared by relaxation experiments, is of the same order of magnitude as that involved in the quasiequilibrium state probed by the ac susceptibility measurements. © 1996 American Institute of Physics. [S0021-8979(96)73508-3]

I. INTRODUCTION

Magnetic viscosity experiments have proven to be a very valuable means to explore the dynamics of spin systems in magnetic materials. The standard way to perform a measurement of magnetic viscosity is by means of relaxation experiments.^{1,2} In a relaxation experiment, the decay of the magnetization of a system after a stepwise change of the applied magnetic field is measured. The typical step-field amplitude is large, comparable to or greater than the coercive field. In the appropriate time window the relaxation is at least approximately logarithmic with time. The proportionality factor $S(T)$ between the magnetization and the logarithm of the time is called magnetic viscosity:

$$M(t)/M_0 = 1 - S(T) \ln(t/t_0), \quad (1)$$

where M_0 is the value of the magnetization at the beginning of the logarithmic relaxation.

The phenomenon is usually attributed to the existence of a collection of simple exponential relaxations with distributed time constants.³ Magnetic systems exhibiting hysteresis are characterized by a distribution of energy barriers. The sudden magnetization reversal used in the relaxation experiments brings the system into a new configuration far from its equilibrium state. Each portion of the system which is trapped in a metastable state relaxes toward a stable state either by thermal activation or by any nonthermal process

like quantum tunneling. The lifetime of the metastable state is related to the barrier energy parameters. Thus magnetic viscosity experiments probe the energy barriers distribution features.

In addition linear ac susceptibility and thermal equilibrium noise experiments have been shown⁴⁻⁷ to give a means to perform magnetic relaxation measurements. In many magnetic systems the equilibrium magnetization noise shows, in the low frequency range, a $1/f$ power spectrum. This originates, via the standard fluctuation-dissipation formula, from a frequency independent imaginary part $\chi''_0(T)$ in the ac susceptibility. This is measured in the linear response regime where the typical amplitude of the field applied to the sample is much lower than the coercive field. The frequency independent imaginary susceptibility $\chi''_0(T)$ translates, in the time domain, into a logarithmic relaxation^{6,7} with velocity:

$$dM/d \ln(t) = (2/\pi)\chi''_0(T)H_0. \quad (2)$$

Thus the measurement of the ac linear imaginary susceptibility $\chi''_0(T)$ is the thermal equilibrium analogous to the measurement of the magnetic viscosity $S(T)$.

At thermal equilibrium the picture of magnetic subsystems relaxing outside a metastable state should be rephrased in terms of subsystems whose magnetization is hopping between nearby free energy minima.⁸ Both the barrier features and the energy splitting between the minima now

affect the dynamics of the systems and thus both the susceptibility and the related thermal magnetic noise.⁸

The two experimental methods operate at scales of field and magnetization variations that differ by orders of magnitude. Thus it is worth asking whether the involved energy distributions can be the same.

The question has become more puzzling in connection with the problem of the macroscopic quantum tunneling of magnetic systems. Indeed both kinds of experiments have observed dependencies of $S(T)$ or $\chi_0''(T)$ on the temperature which could possibly be explained by assuming an underlying quantum tunneling mechanism.

In the present article we give for the first time the results of the simultaneous measurement of the magnetic viscosity, the linear susceptibility, and the equilibrium thermal noise on a sample of the superparamagnetic alloy $\text{Cu}_{90}\text{Co}_{10}$. The comparison between the two sets of data shows that the barrier energy height distributions involved in the two experiments are of the same order of magnitude.

II. EXPERIMENTAL METHODS AND RESULTS

The sample studied is a $\text{Cu}_{90}\text{Co}_{10}$, 60- μm -thick, 5-mm wide rapidly quenched ribbon, prepared by planar flow casting. As shown by x-ray diffractometry,⁹ the Cu and Co phases are immiscible and the Co forms very small clusters of fcc ordered phase.

Both the dc magnetic measurements and the relaxation measurements have been carried out using a commercial rf superconducting quantum interference device (SQUID) magnetometer in the temperature range of 2–300 K. The magnetization versus applied field at room temperature, has been measured and the data fitted to the Langevin law. Thus an estimation of the average diameter $\langle d \rangle$ of the Co magnetic clusters with a value of $\langle d \rangle = 4.2$ nm has been obtained.

The magnetization has been measured both with the zero-field cooling (ZFC) and the field cooling (FC) procedures.¹ A blocking temperature¹ $T_B = 16$ K has been found. Below this temperature the sample exhibits hysteresis.

For the measurement of the magnetic viscosity versus temperature, the magnetization decay at each temperature has been measured in a time window of 2 h. The sample is cooled down to the desired temperature in an applied field $H_1 = 8 \times 10^3$ A/m and then the magnetization is reversed by suddenly switching the field to the new value of $H_2 = -8 \times 10^3$ A/m. The magnetization has been found to follow a logarithmic decrease with time. The magnetic viscosity values $S(T)$ reported in Fig. 1 are obtained by fitting Eq. (1) to the data. The figure shows that the viscosity depends linearly on the temperature. A best fit to the data gives a slope $dS/dT = (4.8 \pm 0.2) \times 10^{-3} \text{ K}^{-1}$. The data do not extrapolate to zero at $T = 0$ K.

The complex susceptibility and magnetic noise measurements have been performed in the temperature range of 1.1–4.2 K. The experimental setup has already been described.¹⁰ Here we only recall that the method basically consists of measuring the complex self-inductance $L(\omega) = L'(\omega) + iL''(\omega)$ of a superconducting transformer coupled to the SQUID on one side and to the sample on the other. At each

FIG. 1. The magnetic viscosity $S(T)$ as a function of the temperature.

temperature, the self-inductance is measured as a function of the frequency. During the measurement the ac field variation applied to the sample has been $H_0 \approx 8 \times 10^{-4}$ A/m.

The data for $L(\omega)$ are converted to the complex susceptibility using standard formulas for coils. The inaccuracy due to geometrical factors affects the calculated value of the susceptibility, the error being larger for samples with a real susceptibility of less than unity, like the present one. However this does not affect the comparison with the noise data. In fact the Nyquist formula only contains the imaginary part $L''(\omega)$ of the inductance,

$$S_\phi(\omega) = 2k_B T (M_{SQ}^2 / |L(\omega)|^2) [L''(\omega) / \omega] + S_0, \quad (3)$$

where $S_\phi(\omega)$ is the noise spectral density at the SQUID output, M_{SQ} is the mutual inductance between the transformer and the SQUID, and S_0 is the noise of the SQUID in the absence of the sample.

The measured values of $S_\phi(\omega)$ have been found to show a $1/f$ shape and to agree without any adjustable parameter with the spectra calculated from the measured inductance data through formula (3). The consistency of the two sets of data demonstrates the thermal equilibrium of the sample at the measured temperature T .

The imaginary susceptibility has been found to be frequency independent at each temperature in the frequency range of 0.01–10 Hz. The frequency independent imaginary susceptibility $\chi_0''(T)$, both the data directly observed and those derived from the noise via Eq. (3), are shown in Fig. 2 as a function of the temperature. The figure shows that $\chi_0''(T)$ depends linearly on the temperature. A best fit of the data gives a slope $d\chi_0''/dT = (3.2 \pm 0.3) \times 10^{-3} \text{ K}^{-1}$.

III. DISCUSSION

It is natural to compare, through Eqs. (1) and (2), the rates of logarithmic relaxation obtained by the two experimental methods: $(1/H_0)[dM/d \ln(t)] = (2/\pi)\chi_0''(T) \approx 1.2 \times 10^{-2}$ ($T = 4.2$ K) and $S(4.2 \text{ K}) \approx 1.5 \times 10^{-2}$. As the two quantities are found at least to be in an order of magnitude

FIG. 2. The imaginary susceptibility $\chi_0''(T)$ as a function of temperature. Open symbols represent the as-measured data. Closed symbols represent the data calculated from noise via Eq. (3). The continuous line represents the linear best fit to the data.

agreement let us discuss if this agreement is coincidental or if instead it can be explained by looking at the underlying physical picture.

The escape of the magnetization from a metastable state occurs as an exponential relaxation, $dM/dt \propto e^{-\Gamma t}$, where Γ is the decay rate. If the escape is thermally activated, the decay rate follows the Arrhenius law $\Gamma = \Gamma_0 \exp(-U/k_B T)$, with U the energy barrier height and Γ_0 the attempt frequency. It is known that by invoking the collective contribution of many exponentially relaxing subsystems with suitably distributed rates Γ one can explain the observed logarithmic time law.³ To be specific, it has been shown that by integrating over a wide and smooth enough distribution of U , the magnetic viscosity becomes^{1,11}

$$S(T) = k_B T / \langle U \rangle \quad (4)$$

where, $\langle U \rangle$ is the average activation energy. As $S(T)$ does not extrapolate to zero at $T=0$, the model describes the experiment only qualitatively. However to get a broad estimate of $\langle U \rangle/k_B$ one can use the highest available temperature data, $T=4.2$ K, to get $\langle U \rangle/k_B \approx 300$ K.

$\langle U \rangle$ also determines the temperature at which the magnetization reaches a maximum in the ZFC magnetization process^{1,11} and is then related to the blocking temperature by $\langle U \rangle \approx 30 k_B T_B$. This gives $\langle U \rangle/k_B \approx 500$ K. Notice that this value is not far off the upper limits one gets when estimating the overall anisotropy energy of a grain, $U \approx K V_g$, with V_g indicating some average value of the volume of a single grain and K the anisotropy constant. Taking⁹ $K \approx 3 \times 10^5$ J/m³ and V_g from the figure quoted in the previous section, one gets $U/k_B \approx 1000$ K.

As already stated, the description of the system behavior at thermal equilibrium is based on a collection of two-level systems. The local magnetization overcomes the barrier between two nearby free energy minima, which are in general nondegenerate. The escape rate is then the sum of the rates of the two minima, the ratio of which has to agree with thermal

equilibrium requirements.^{7,8} If the escape is due to thermal activation, if the energy barrier heights are distributed, and if the energy Δ of separation between the minima is also distributed up to a maximum value Δ_{\max} and $\Delta_{\max} \gg k_B T$, then the frequency independent imaginary susceptibility is linear with the temperature:

$$\chi_0'' \approx (N_g V_g / V_s) (\mu_0 M_g^2 V_g / \Delta_{\max}) (k_B T / \langle U \rangle), \quad (5)$$

where N_g and M_g are the total grain number and the grain magnetization, respectively, and V_s is the sample volume. Equation (5) is taken from Ref. 8 with the additional factor $N_g V_g / V_s$ due to the dilution of the clusters within the sample. By comparison with Eqs. (4) and (5) this gives

$$\chi_0'' \approx (N_g V_g / V_s) (\mu_0 M_g^2 V_g / \Delta_{\max}) S(T). \quad (6)$$

The first factor, the dilution, can be estimated to be $(N_g V_g / V_s) \approx 0.1$. Thus in order to explain the observed agreement one should have $(\mu_0 M_g^2 V_g / \Delta_{\max}) \approx 10$.

If the energy splitting Δ of the two-level system is of dipolar origin, then $\Delta = \mu_0 \mathbf{m} \cdot \mathbf{H}$ with \mathbf{m} the total cluster magnetic moment and \mathbf{H} the local value of the magnetic field. The maximum Δ_{\max} is attained for antiparallel vectors and is $\Delta_{\max} = \mu_0 M_g V_g H_{\max}$, with H_{\max} the maximum value of the field experienced by the grain so that $(\mu_0 M_g^2 V_g / \Delta_{\max}) \approx M_g / H_{\max}$. To quantitatively evaluate H_{\max} is difficult. Estimating H_{\max} as the mean magnetization of the sample and taking M_g in the range of values observed for cobalt and cobalt alloys, one gets $1 \leq (\mu_0 M_g^2 V_g / \Delta_{\max}) \leq 100$ which is in the right range to explain the observed agreement.

The data so far presented and discussed are consistent with the thermal activation regime as no crossover to a non-thermal behavior has been detected yet with either technique. The above discussion predicts that if a crossover exists to a quantum regime, both methods should detect it at the same temperature T_c . Quantum tunneling theories predict^{1,11} for the present sample $T_c \approx 0.1$ K. Experiments are in progress to verify this prediction.

Simultaneous molecular and spin dynamics: Quasiclassical approximation and quantum effects

V. P. Antropov and B. N. Harmon

Ames Laboratory and Department of Physics & Astronomy, Iowa State University, Ames, Iowa 50011

We sketch the derivation of a set of equations of motion for the simultaneous treatment of both molecular and spin dynamics. The equations can be extended through the concept of imaginary time density functional theory, to describe the penetration of classically forbidden regions. © 1996 American Institute of Physics. [S0021-8979(96)73608-3]

First principles calculations of spin dependent electronic structures have been restricted to $T=0$ K, static magnetic moment (MM) configurations. To overcome these limitations we have recently proposed a method¹ which allows the torque on individual MM to be obtained and their dynamics evaluated, much in the way *ab initio* temperature dependent molecular dynamics is presently performed. Here we give more details about the description of simultaneous spin and molecular dynamics announced in Ref. 1, and discuss how several quantum effects can be included within the present formalism. An application for fcc Fe can be found in Ref. 1.

There are several ways at arriving at the final equations. Here we follow a quite general approach involving the time dependent WKB method for the adiabatic and quasiclassical approximations. In the former one obtains the adiabatic limit when there is a large difference in characteristic time scales between various degrees of freedom (e.g., nuclei and electrons), while in the latter one obtains the quasiclassical limit when the length over which the potential changes is much larger than the electron wavelength.²

We start from the basic time-dependent Schrödinger equation

$$i\frac{d}{dt}\Psi = \hat{H}\Psi, \quad (1)$$

where \hat{H} is the total Hamiltonian,

$$\hat{H} = -\sum \frac{\nabla_{\mathbf{R}}^2}{2M} + V_{II} - \sum \frac{\nabla_{\mathbf{r}}^2}{2m} + V_{ee} + V_{Ie} \quad (2)$$

(for simplicity we will omit electron spin indices for the time being). Here indices I and e are ionic and electronic indices, respectively. We can separate the wave function in a manner convenient for applying subsequent approximations

$$\Psi = C(t)U_s U_{\mathbf{R}} \Phi(\mathbf{R}, t) \psi(\mathbf{R}, \mathbf{r}, t), \quad (3)$$

where $C(t)$ is the semiclassical caustic,

$$U_{\mathbf{R}} = \exp\{iS(\mathbf{R}, t)\} \quad (4)$$

and

$$U_s = \exp\{S_s(\mathbf{r}, t)\} = \exp\{\lambda \sigma_- - \lambda^* \sigma_+\}. \quad (5)$$

In Eq. (5) λ chosen to diagonalize the Hamiltonian in spin space, is some function of angles related to the direction of the internal magnetic field \mathbf{B} and, in general, is a function of electronic coordinates.

We first assume that the S function changes slowly in time and in space, then the time-dependent WKB approach starts from the expansion

$$S(\mathbf{R}, t) = S(\mathbf{R}_0, t_0) + \int_{\mathbf{R}_0}^{\mathbf{R}} \nabla_{\mathbf{R}} S d\mathbf{R} + \int_{t_0}^t \nabla_t S dt. \quad (6)$$

To find possible trajectories we have to optimize the quantum mechanical action

$$L = \int_{t_0}^t dt \left\langle \Psi \left| i\hbar \frac{\partial}{\partial t} - \hat{H} \right| \Psi \right\rangle \quad (7)$$

using the set of wave functions from Eqs. (3)–(5). Simple but tedious variational calculations (relative to ψ) lead us to the next electronic equation

$$i\frac{\partial \psi}{\partial t} = H\psi + \gamma_I \psi + \gamma_s \psi, \quad (8)$$

where the electronic Hamiltonian is written as

$$H = \left(-\sum \nabla_{\mathbf{r}}^2 + V_{ee}(\mathbf{r}) + V_{eI}(\mathbf{r}, \mathbf{R}) + \frac{1}{2} \sum \sigma_{z_i} B_{z_i} \right) \psi, \quad (9)$$

with site-dependent spin coordinate systems. The additional terms in Eq. (8) are

$$\gamma_I = \sum \int_{t_0}^t (\mathbf{P} d\mathbf{R} + \mathbf{R} d\mathbf{P}), \quad (10)$$

a molecular phase factor,³ and the factor

$$\gamma_s = \sum (\alpha \dot{\alpha}^* - \alpha^* \dot{\alpha}) \frac{\sigma_z}{2} = \sum \frac{\sigma_z}{2} \int dt \dot{\phi} (1 - \cos \theta), \quad (11)$$

where $\alpha = \xi/(1+|\xi|^2)^{1/2}$ and $\xi = \exp(-i\phi) \tan \theta/2$, is directly connected with the spin geometric phase.³ It is worthwhile to note that these additional terms in the Hamiltonian are not kinetic or potential energy terms. Their appearance is associated with the reduction of some of the degrees of freedom in the original wave equation.

To install the connection with the well known adiabatic approach we note that in this derivation the following terms have been dropped in the above equations:

$$H_{Ie}^{\text{off}} = \Phi^2 \psi^* \nabla_{\mathbf{R}}^2 \psi + 2\Phi \psi^* \nabla_{\mathbf{R}} \Phi \nabla_{\mathbf{R}} \psi \quad (12)$$

and

$$H_{wp} = \psi^* \psi \Phi \nabla_{\mathbf{R}}^2 \Phi \quad (13)$$

in order to remove non-adiabatic ion–electron interactions and the wavepacket motion explicitly. At the same time we have dropped a spin flip term $H_{es}^{\text{off}} \sim A\sigma_- + A^*\sigma_+$ which would otherwise appear in Eq. (8).

The terms (12) which arise from the time-dependent WKB and adiabatic approximation are exactly the terms dropped in the adiabatic molecular dynamics (Born–Oppenheimer) equations of motion. The term (13) is a separate term arising in the WKB approach and is associated with the motion of the ionic wavepacket. The extraction of the analogous terms for the spin motion is more complicated because in general the angles of the MM are functions of the electronic coordinates. In order to arrive at a set of computationally feasible dynamical equations in which the spin term γ_s can be treated as a pure phase factor we need to remove the dependence on electronic coordinates. This may be accomplished by assuming about each site (e.g., within a muffin-tin sphere or an atomic polyhedra) that the spin or moment density direction is independent of the spatial coordinates. The dynamics of the local moment will then correspond to a “rigid” spin approximation (RSA).

Finally the total wave function can be written as

$$\Psi(\mathbf{R}, \mathbf{r}, t) = \sum C(t) \Phi(\mathbf{R}_0, t_0) \times \exp[\gamma_I + \gamma_s + \delta\omega/4] \psi(\mathbf{R}, \mathbf{r}, t), \quad (14)$$

where ω is a vector of fundamental frequencies of the trajectory and δ is a vector of Maslov indices, associated with the quantum effects of zero point motion.⁴ Then we obtain for the equations of the slow degrees of freedom (obtained by extremizing the corresponding classical trajectories)

$$\dot{\mathbf{P}} = -\nabla_{\mathbf{R}} V_{II} - \langle \psi | \nabla_{\mathbf{R}} V_{eI} | \psi \rangle; \quad M\dot{\mathbf{R}} = \mathbf{P}, \quad (15)$$

for the ionic coordinates, and for each site we have

$$\begin{aligned} \dot{\alpha} &= \frac{\partial V_{ss}}{\partial \alpha^*} + \langle \psi | \frac{\partial V_{es}}{\partial \alpha^*} | \psi \rangle; \\ \dot{\alpha}^* &= -\frac{\partial V_{ss}}{\partial \alpha} - \langle \psi | \frac{\partial V_{es}}{\partial \alpha} | \psi \rangle \end{aligned} \quad (16)$$

for the MM orientation. The corresponding EOM for the fast electronic degrees of freedom has the form

$$i\frac{\partial \psi}{\partial t} = H\psi, \quad (17)$$

where H is given in Eq. (9). In Eq. (16) we have separated the spin dependent potential into a term V_{ss} , which gives the torque due to the interaction among the rigid moments, and a second term which involves the coupling to the electronic degrees of freedom and contains non-classical corrections such as orbital and coordinate dependence. This whole set of equations is suitable for the description of time dependent processes in chemical reactions and solids where magnetic or spin effects play a role. The forces in (15) became the usual Hellmann–Feynman forces in the adiabatic limit.

Now we would like to discuss the opportunity to add some stationary quantum corrections to this dynamics (the semiclassical quantization of levels and tunneling effects). A

FIG. 1. Tunneling splitting as function of the potential well.

first approach to quantization using these dynamical equations is to solve Eq. (15) in the classical region and use the semiclassical Einstein–Brillouin–Keller quantization rules (see, for instance, Ref. 5). For tunneling effects one must consider motion in the non-classical region. This can be done using the formalism of the classical EOM with an imaginary time ($t \rightarrow i\tau$), which allows a description of motion in the classically forbidden region. Such modified EOM can be written in simplest form as

$$M \frac{\partial^2}{\partial \tau^2} \mathbf{R} = \nabla_{\mathbf{R}} V, \quad i \frac{\partial}{\partial \tau} \alpha = \frac{\partial V_{ss}}{\partial \alpha^*} \quad (18)$$

$$\frac{\partial \psi}{\partial \tau} = H\psi. \quad (19)$$

The discussion of the imaginary time dynamics itself can be found in Refs. 2,6,7,8. The set of coupled equations (15)–(19) should be solved simultaneously with the real time and nuclear coordinates treated in Eq. (19) for the $\psi = \psi(\mathbf{r}, \tau; \mathbf{R}, t)$ as parameters. The quantity to be estimated is

$$\gamma = \int_{-T/2}^{T/2} d\tau \left\langle \psi(-\tau) \left| \frac{\partial}{\partial \tau} \right| \psi(\tau) \right\rangle, \quad (20)$$

which can be considered as an alternative to Eq. (10)–(11) and represents the exponential factor in the expression for the shift in energy levels of oscillator due to quantum tunneling⁹

$$\delta E_n = K^{2n+1} \exp\{-\gamma\} / 2^n \omega^{n-1/2} n!, \quad (21)$$

where K is the exponential prefactor, n is a quantum level, and ω is a frequency related to the potential minimum. In general the question of how to search for the optimal path of such dynamics is very complicated. For imaginary time dynamics of the ground state (instanton dynamics) and symmetrical systems, such paths can be found fairly easily.⁸ It is worthwhile to note that an alternative approach is to solve the classical Eq. (15) in the forbidden region using complex coordinates (or angles).² It is unclear at the moment which technique will be more suitable for real systems.

Let us illustrate the quantum dynamics described above by using a simple potential curve shown in Fig. 1. The regions I and II represent locally two well potential situations, which can be reached independently at the real time moments t_I and t_{II} by solving Eq. (15), with the corresponding classical (for the nuclei) total energy minima E_I and E_{II} ($E_I < E_{II}$). The tunneling (exchange) taking place at t_I and t_{II} gives an additional energy (21). The quantum corrections

change the classical ground state from $E'_I = E_I + \delta E_I$ to $E'_{II} = E_{II} + \delta E_{II}$ and stabilize the geometry of region II more strongly than that of region I. Also the double well potential having in the classical description two degenerate states (with the system classically choosing only one well in the ground state and breaking symmetry), with the addition of imaginary time dynamics, has a unique symmetric ground state.

The above discussions concerning spin dynamics are based on the adiabatic use of the stationary Schrödinger equation to evaluate the system's path. The effects of temperature can be incorporated in the SD equations in a manner analogous to the adding of a thermal bath to MD simulations,¹ however, for spin systems the implementation of a thermal reservoir is less evident than for a MD simulation of ions governed by classical EOM. The result of the thermalization should be the introduction of fluctuations so that the local spin relative to the local exchange field direction has an average alignment given by the Brillouin function. Spin systems may also be generalized to include non-classical, or quantum, effects. Already the EOM for SD, Eq. (16), contain the quantum terms V_{es} . It may also be possible to introduce temperature at the quantum level. For instance, in Ref. 10 it has been shown how to introduce thermal effects at the quantum level so that the generated wave functions are ergodic. The generalization of this technique to *ab initio* molecular or spin dynamics (in a sort of classical-quantum hybrid) looks like a promising way to obtain quantum statistical effects (e.g., the Bloch law for the low temperature magnetization and the Debye law for specific heat in MD).

The application of the classical SD described above has been shown to be quite successful in finding many new magnetic phases in fcc Fe,¹ and looks promising as a method for classical temperature simulations. The description of quantum effects is possible and can be implemented as a natural extension of the methods described above.

We would like to thank M. I. Katsnelson and M. van Schilfgaarde for many discussions. This work was carried out at the Ames Laboratory, which is operated for the U. S. Department of Energy by Iowa State University under Contract No. W-7405-82. This work was supported by the Director for Energy Research, Office of Basic Energy Sciences of the U. S. Department of Energy.

Magnetic exchange coupling mediated by bound states

C. A. R. Sá de Melo

Argonne National Laboratory, Materials Science Division, Argonne, Illinois 60439

Usually indirect exchange coupling is mediated by unbound, noncorrelated intermediate states (RKKY-like mechanisms) or by unbound, correlated intermediate states (superexchange-like mechanisms). Here we investigate the possibility of indirect magnetic exchange coupling mediated by bound, correlated intermediate states. As a concrete example we study the magnetic coupling between two magnetic impurities embedded in a semiconductor matrix. The importance of long ranged attractive Coulomb interactions between electrons and holes is emphasized. This attraction leads to exciton bound states which act as mediators of the effective exchange interaction between the two impurities. The resulting exchange interaction presents strong temperature dependence and can be analyzed in terms of the symmetry of the internal wavefunction of the exciton bound states. Possible applications of these results may include recent experimental results on ferromagnetic metal-semiconductor multilayers. © 1996 American Institute of Physics.

[S0021-8979(96)73708-X]

Typically, indirect magnetic exchange interactions are thought of as being mediated by unbound, non-correlated intermediate states as it is the case for RKKY-like mechanisms when applied to metals¹ or to semiconductors.² In addition, the indirect magnetic exchange interaction is also thought as being mediated by unbound, correlated intermediate states as it is the case for the superexchange-like mechanisms when applied to insulating transition metal oxides.³ Our main aim in this paper is to describe a situation which is completely different from the two described above. Namely a case where the indirect magnetic exchange coupling is mediated by a bound, correlated intermediate state. The choice of a system to study the proposed effect is very important. We choose to study the concrete example of the indirect magnetic exchange between two magnetic impurities embedded in a semiconductor matrix, which may be extended to the case of a magnetic impurity lattice. Our analysis is not only of academic interest but also may be relevant to recent experiments on ferromagnetic metal-semiconductor multilayers like Fe/FeSi,⁴ Fe/Si,⁵ MnTe/CdTe, and EuTe/PdTe⁶ and possibly to other systems like Fe/GaAs yet to be synthesized.

Now let us briefly discuss the central physical picture of the mechanism. Consider two magnetic impurities inside of a direct gap semiconductor and allow an attractive Coulomb interaction between an electron in the conduction band and a hole in the valence band. The Coulomb interaction binds electron-hole pairs into excitons, which exist in the gap of the semiconductor (excitons are stable bound states with relatively long lifetimes). As a result, these bound states provide intermediate states inside the gap which can mediate the exchange of spin information between the two magnetic impurities. This mediation is possible since excitons, although chargeless, can carry spin information, i.e., can be singlet or triplet. It is also important to emphasize that these bound states inside the gap can mediate the indirect magnetic coupling more effectively than the unbound electron-hole pairs, which have energies greater than the gap size.

As a result of the existence of these bound states inside the gap of the semiconductor, the magnetic exchange cou-

pling increases with temperature. This increase in the indirect coupling with increasing temperature is a natural consequence of the population increase of these bound states caused by thermal excitations. In addition to this thermal effect, we shall see that the finite extension of the excitons internal wavefunctions and their symmetries play an important role in the determination of the *magnitude* and *sign* of the effective exchange coupling J_{eff} .

Let us begin our analysis with the choice of the model and the geometry. First, let us study the situation of two magnetic impurities embedded in an isotropic and direct gap semiconductor matrix in order to establish the basic mechanism of the effective magnetic exchange. The starting Hamiltonian is of the following form

$$H = H_a + H_c + H_v + H_{cv} + H_{acv}, \quad (1)$$

where $H_a = \sum_{i,\sigma} \epsilon_{\sigma} C_{\sigma}^{\dagger}(R_i) C_{\sigma}(R_i)$ is the kinetic energy term of the magnetic impurities located at positions R_i , with $i=1,2$; $H_c = \sum_{k_e, \sigma_e} \epsilon_c(k_e) f_{c, \sigma_e}^{\dagger}(k_e) f_{c, \sigma_e}(k_e)$ is the kinetic energy for the conduction electrons in the semiconductor matrix, with $\epsilon_c(k_e) = E_c + k_e^2/2m_e - \mu$; the term $H_v = \sum_{k_h, \sigma_h} \epsilon_v(k_h) f_{v, \sigma_h}^{\dagger}(k_h) f_{v, \sigma_h}(k_h)$ is the kinetic energy of the valence electrons with dispersion $\epsilon_v(k_h) = E_v - k_h^2/2m_h - \mu$. Here the gap of the semiconductor is $E_g = E_c - E_v$. The Coulomb interaction between an electron in the conduction band and a hole in the valence band is

$$H_{cv} = \sum' V_{\sigma_e, \sigma_h}(q) f_{c, \sigma_e}^{\dagger}(k_e + q) f_{c, \sigma_e}(k_e) \\ \times f_{v, \sigma_h}^{\dagger}(k_h - q) f_{v, \sigma_h}(k_h)$$

with the summation ('') being over $(k_e, k_h, q, \sigma_e, \sigma_h)$, and $V_{\sigma_e, \sigma_h} = 4\pi e^2/(\epsilon q^2)$, where ϵ is the dielectric constant of the semiconductor. Finally,

$$H_{acv} = - \sum'' \tilde{J} f_{c, \sigma_e}^{\dagger}(k_e) f_{v, \sigma_h}(k_h) C_{\sigma_e}^{\dagger}(R_i) C_{\sigma_h}(R_i) + h.c.$$

is the *exchange* interaction between the local magnetic impurity and an electron in the conduction band and a hole in the valence band. Here, the summation (') is over

$(k_e, k_h, \sigma, \sigma', \sigma_e, \sigma_h); \tilde{J} = J_{\sigma_e, \sigma_h}^{\sigma, \sigma'}(k_e, k_h) \exp[i(k_h - k_e) \cdot R_i]$ is the exchange coupling and the spin conservation function $\tilde{\delta} = \delta_{\sigma_e, \sigma} \delta_{\sigma_h, \sigma'}$.

We continue our approach by constructing the action of the system

$$S = \int_0^\beta d\tau [K(\tau) - H(\tau)]$$

where $K(\tau) = K_a + K_c + K_v$, with the first term being $K_a = \sum_{i, \sigma} C_{\sigma}^{\dagger}(R_i, \tau) \partial_{\tau} C_{\sigma}(R_i, \tau)$, the second being $K_c = \sum_{k_e, \sigma_e} \int_{c, \sigma_e}^{\dagger}(k_e, \tau) \partial_{\tau} f_{c, \sigma_e}(k_e, \tau)$ and the last being $K_v = \sum_{k_h, \sigma_h} \int_{v, \sigma_h}^{\dagger}(k_h, \tau) \partial_{\tau} f_{v, \sigma_h}(k_h, \tau)$. Now we use the functional integral formalism to derive the effective action which involves only the fermion variables of the magnetic atoms. Upon functional integration of the valence and conduction fermions with actions $S_c = \int_0^\beta d\tau [K_c - H_c]$, $S_v = \int_0^\beta d\tau [K_v - H_v]$ and interaction actions $S_{cv} = -\int_0^\beta d\tau H_{cv}(\tau)$ and $S_{\ell cv} = -\int_0^\beta d\tau H_{\ell cv}(\tau)$ we obtain

$$\int Df^{\dagger} Df \exp[S_c + S_v + S_{cv} + S_{\ell cv}] \approx \exp[S_{\text{eff}}]$$

and arrive at the effective action $S_{\text{eff}} = -H_{\text{eff}}$.

When $\tilde{J} = J$, i.e., \tilde{J} is spin and momentum independent, the magnetic part H_{mag} of H_{eff} takes the Heisenberg form

$$H_{\text{mag}}(\mathbf{R}_{12}) = - \sum_{i\omega} \tilde{J}_{\text{eff}}(\mathbf{R}_{12}, i\omega) \mathbf{S}_1(i\omega) \cdot \mathbf{S}_2(-i\omega). \quad (2)$$

The effective exchange \tilde{J}_{eff} can be calculated in the limit of low density of electrons and holes by solving the Bethe-Salpeter equation.⁸⁻¹⁰ The usual procedure in the evaluation of the interaction Hamiltonian H_{mag} as defined in (2) is to analyze the static limit $i\omega = 0$ and thus obtain the interaction $\tilde{J}_{\text{eff}}(\mathbf{R}_{12}, i\omega = 0)$. In the approximation considered here this limit would mean the complete absence of temperature dependence in $\tilde{J}_{\text{eff}}(\mathbf{R}_{12}, i\omega = 0)$, which would be uninteresting from our point of view. Thus, we do not discuss this limit here. Here, we will be concerned only with the instantaneous part of H_{mag} ,

$$\tilde{J}_{\text{eff}}(q, \tau = 0) = \frac{|J|^2}{T} \sum_{\lambda} N_B[\omega_{\lambda}(q)] R_{\lambda}(q), \quad (3)$$

with N_B being the Bose function. Here, $R_{\lambda}(q) = \sum_k \phi_k^*(k; q) \phi_{\lambda}(k; q)$, where the auxiliary functions $\phi_{\lambda}(k; q) = \int d\mathbf{r} \exp[i\mathbf{k} \cdot \mathbf{r}] \exp[i\gamma \mathbf{q} \cdot \mathbf{r}] \xi_{\lambda}(\mathbf{r})$ are expressed in terms of the hydrogenic wave functions $\xi_{\lambda}(\mathbf{r})$ for the relative coordinate of the electron-hole bound state (exciton) with quantum numbers $\lambda \equiv (n, \ell, m)$. The corresponding eigenenergies are $\omega_{\lambda}(q) = E_g - \mathcal{R}/n^2 + \hbar^2 q^2/2M$, where $M = m_e + m_h$, $\mathcal{R} = \mu R_y/(m_e \epsilon^2)$ with μ being the reduced mass of the bound electron-hole pair and $R_y = 13.6$ eV being the Rydberg. The characteristic size of the bound electron-hole pair in the state $\lambda \equiv (n, \ell, m)$ is $r_{eh} = n^2 a_0$ where $a_0 = \epsilon(m/\mu)a_B$ is the Bohr radius of the electron-hole problem, while $a_B = 0.529$ Å is just the Bohr radius for the hydrogen atom. In addition, the parameter $\gamma = \Delta m/2M$, where $\Delta m = m_e - m_h$.

In the Boltzmann limit ($\min[\omega_{\lambda}(q)] \gg T$) the integration over momentum \mathbf{q} in (3) is performed to obtain

$$\tilde{J}_{\text{eff}}(\mathbf{R}_{12}, \tau = 0) = \sum_{\lambda} J_{\lambda}(\mathbf{R}_{12}), \quad (4)$$

where

$$J_{\lambda}(\mathbf{R}_{12}) = \frac{|J|^2}{T} \exp[-E_{\lambda}/T] M_{\lambda}(T) \quad (5)$$

is an effective coupling that depends on the internal quantum numbers $\lambda \equiv (n, \ell, m)$ of the bound state via the dimensionless matrix element

$$M_{\lambda}(T) = \int d\tilde{\mathbf{r}}_1 d\tilde{\mathbf{r}}_2 \tilde{\xi}_{\lambda}(\tilde{\mathbf{r}}_1) \tilde{U}(\tilde{\mathbf{R}}_{12}, \tilde{\mathbf{r}}_{12}, \alpha) \tilde{\xi}_{\lambda}^*(\tilde{\mathbf{r}}_2), \quad (6)$$

with the effective dimensionless potential being

$$\begin{aligned} \tilde{U}(\tilde{\mathbf{R}}_{12}, \tilde{\mathbf{r}}_{12}; \alpha) &= \frac{2^{3/2}}{\alpha^3} \exp[-(\gamma \tilde{x}_{12})^2/\alpha^2] \\ &\times \exp[-(\gamma \tilde{y}_{12})^2/\alpha^2] \\ &\times \exp[-(\tilde{Z}_{12} - \gamma \tilde{z}_{12})^2/\alpha^2] \end{aligned} \quad (7)$$

and the dimensionless wavefunctions being $\tilde{\xi}_{\lambda}(\tilde{\mathbf{r}}) = a_0^{3/2} \xi_{\lambda}(\mathbf{r})$. Here, $\alpha = a_T/a_0$, where $a_T = \hbar \sqrt{2/MT}$ is the characteristic thermal length and a_0 is the characteristic Bohr radius of the electron-hole bound state. In (7), without loss of generality, we have chosen the z axis of our system to be along the line that connects the two impurities, thus we defined $\mathbf{R}_{12} \equiv Z_{12}$, i.e., $X_{12} = Y_{12} = 0$. It is very important to notice in (4) that the coupling J_{λ} changes sign depending on the sign of M_{λ} .

The dimensionless effective potential \tilde{U} is of crucial importance in establishing the strength of the matrix element M_{λ} and thus determining \tilde{J}_{eff} . The most interesting case occurs when $\alpha \ll 1$, i.e., when the thermal length a_T is much smaller than the characteristic Bohr radius a_0 . In this case the potential $\tilde{U} \gg 1$ and the coupling J_{λ} can be appreciable. The most interesting limit occurs when $\alpha \rightarrow 0$, in which case

$$\tilde{U} = (2\pi)^{3/2} \delta(\gamma \tilde{x}_{12}) \delta(\gamma \tilde{y}_{12}) \delta(\tilde{Z}_{12} - \gamma \tilde{z}_{12}) \quad (8)$$

and the matrix element

$$M_{\lambda} = \frac{(2\pi)^{3/2}}{|\gamma|^3} \int d\tilde{\mathbf{r}}_1 \tilde{\xi}_{\lambda}(\tilde{x}_1, \tilde{y}_1, \tilde{z}_1) \tilde{\xi}_{\lambda}^*(\tilde{x}_1, \tilde{y}_1, \tilde{z}_1 - \tilde{Z}_{12}/\gamma) \quad (9)$$

is now just a simple overlap integral between the internal bound state wave functions separated by the distance \tilde{Z}_{12}/γ . The final expression for \tilde{J}_{eff} is valid under two conditions. The first corresponds to the Boltzmann approximation, which is valid when $T_0 \equiv \min[\omega_{\lambda}(q)] \gg T$ is satisfied, i.e., $T_0 \gg T$, with $T_0 = E_g - \mathcal{R}$. It is required that T_0 be positive, otherwise there is no bound state inside the gap. The second condition corresponds to $\alpha \ll 1$, which implies $T \gg T_u$, where $T_u = 4(\mu/M)\mathcal{R}$. As a result, the approximation used so far is valid in the temperature range $T_u \ll T \ll T_0$.

We shall now turn our attention to some qualitative aspects of the magnetic coupling J_{λ} . The first important qualitative aspect is the determination of the sign of the magnetic coupling J_{λ} which is in turn governed by the sign of M_{λ} in the temperature range $T_u \ll T \ll T_0$. It is not difficult to convince ourselves that for the $1s$ bound state ($n=1, \ell=0$,

$m=0$) M_{1s} is always positive, thus J_{1s} has always the *ferromagnetic* sign. In the case $n=2$, the $2s$ ($\ell=0$) bound state also produces $M_{2s}>0$ and $J_{2s}>0$. A similar situation also occurs for the $2p_x$ and $2p_y$ ($\ell=1$) bound states. In contrast, a more interesting situation occurs for the $2p_z$ state ($\ell=1$): for small separations $\tilde{Z}_{12}/\gamma \ll 4$, the overlap M_{2p_z} is positive and thus J_{2p_z} has the *ferromagnetic* sign; for large separations $\tilde{Z}_{12}/\gamma \gg 4$, the overlap $M_{2p_z} < 0$ and J_{2p_z} has the *antiferromagnetic* sign. Similar analysis can be also performed for the higher n states, from which the qualitative behavior of M_λ for different orbital ℓ and azimuthal m quantum numbers can be easily extracted from the knowledge of the shapes of the bound state wave functions.

The second important qualitative aspect of J_λ is that in the temperature range of interest ($T_u \ll T \ll T_0$) the matrix element M_λ is temperature independent and thus the magnetic exchange coupling has a simple activated form that can be read off from (5). The exact form of the activated behavior in (5) follows from the Boltzmann approximation used here, but physically it reflects the fact that when the temperature is increased more bound states (inside the gap) are populated and thus they can more effectively mediate the exchange interaction between the impurities. Conversely, when the temperature is lowered there are less bound states thermally populated and as a result the *magnitude* of the magnetic exchange J_λ is reduced.

Our results should be compared with the RKKY-like mechanisms (which neglect long ranged Coulomb interactions) applied to metals¹ and semiconductors.² In the case of metals, where there is good screening, RKKY-like mechanisms have been quite successful in predicting the indirect exchange coupling between two magnetic impurities mediated by unbound particle-hole states, where the coupling oscillates (for large distances) between *ferromagnetic* and *antiferromagnetic* as a function of separation of the impurities.¹ In the case of semiconductors, where the screening is not so good, RKKY-like mechanisms (mediation via unbound electron-hole states) predict for a direct gap semiconductor that the indirect exchange coupling (at large separations) decays exponentially with decay length $\ell_d = [2E_g M]^{-1/2}$ where the *sign* of the coupling is always *ferromagnetic*.² The inclusion of long range attractive Coulomb interaction between conduction electrons and valence holes allows the formation of exciton bound states, which in turn act as mediators of the indirect exchange interaction. As can be inferred from Eq. (5), the decay of J_λ is still exponential at large distances, but its *sign* depends on the *symmetry* of the intermediate (corre-

lated) bound state. This should be compared with the strong dependence of the superexchange interaction³ on the *symmetry* of the intermediate (correlated) unbound states in the context of transition metal oxides.¹¹

To compare our predictions qualitatively with experiments one must first consider the boundary conditions on ferromagnetic-metal/semiconductor multilayers and establish the existence of stable excitons in the semiconductor spacer. Secondly, one needs to identify the dominant *symmetry* of these stable intermediate states. At this stage our results would suggest that for semiconductor spacers with dominant $2s$ -excitons the indirect exchange coupling is *ferromagnetic* for all spacer thicknesses, while for spacers with dominant $2p_z$ -excitons the indirect exchange coupling is *ferromagnetic* at small thicknesses but *antiferromagnetic* at intermediate and larger thicknesses.

Phenomenological description of the magnetization relaxation (abstract)

V. L. Sobolev and Huei Li Huang

Department of Physics, National Taiwan University, Taipei, Taiwan, Republic of China

The dynamics and relaxation of magnetization $\mathbf{M}(\mathbf{r}, t)$ is usually described phenomenologically by the Landau–Lifshitz (LL) equation with relaxation term $\dot{\mathbf{M}} = -\gamma[\mathbf{M} \times \mathbf{F}] + \mathbf{R}$, where γ is the gyromagnetic ratio ($\gamma > 0$), \mathbf{F} is the effective field, and \mathbf{R} describes the relaxation of the magnetization toward its equilibrium value. It is already well known that the relaxation term of either the LL or Gilbert form does not give a correct description of the dependence of spin-wave damping on the wave vector at small wave vectors for the models of an isotropic and easy plane ferromagnet. The correct behavior of the spin wave damping may be obtained by taking into account the spatial dispersion of the relaxation caused by the exchange interaction and correct symmetry structure of the relativistic part of the relaxation term¹ which now has to be represented as a sum of the exchange and relativistic parts by $\mathbf{R} = \mathbf{R}_{\text{ex}} + \mathbf{R}_{\text{r}}$. A review of the recent results on the relaxation obtained in the frames of the LL equation with the relaxation term suggested by Bar'yakhtar is presented. Comparison of the spin wave damping calculated in the frames of the phenomenological and microscopic approaches has been carried out. In particular it is shown that, in the case of yttrium iron garnet or substituted garnets, the estimation of the value of phenomenological constant of the exchange relaxation has to be carried out by properly taking into account the many sublattice magnetic structure of these magnets. Numerical estimations of the phenomenological relaxation constants for the yttrium iron garnet are given. © 1996 American Institute of Physics. [S0021-8979(96)69108-7]

Atomic magnetic moments and spin notion

Xavier Oudet

Laboratoire de Magnétisme et d'Optique de l'Université de Versailles, C.N.R.S., 45 Avenue des Etats-Unis,
78000 Versailles, France

It is shown that there is an energy associated with the spin. Then the electron is considered as a fluid mass and the wave function as a quantification of the mechanical action. This approach enables us to understand why in Dirac's theory just the total angular momentum is a constant of the motion and allows an explanation of the g factor. Then an interpretation of Dirac's equation is proposed putting in view the trajectory of the electron. © 1996 American Institute of Physics.

[S0021-8979(96)73808-6]

I. INTRODUCTION

The spin hypothesis has been proposed to explain the doublet structure of several spectral series. This hypothesis was a real success and it appeared natural that the two lines of a doublet correspond to the two spin states as expressed today by $j=l+1/2$ and $j=l-1/2$. The study of Dirac's theory shows that it is not in this way that one has to understand the properties associated with a doublet and its application to the calculation of the magnetic moments has also brought new evidence of this difficulty. To clarify this difficulty we have revisited some properties characterizing the two lines of a doublet. This study suggests that the electron has to be thought of as a fluid with a volume and that the wave function stands for the mechanical action which leads the electron upon its trajectory. The doublet then corresponds to two different ways to receive the action giving its own rotation to the electron. This model allows an explanation of the Landé factor g as a property of the action with respect to the total angular momentum.

This work is strongly suggested by the previous results obtained with the calculation of the magnetic moment that we wish now to recall shortly. Indeed with the spin hypothesis the electron has been thought as a small rigid mass having an additional angular momentum which is supposed to be added to or subtracted from the orbital angular momentum. But with such a conception the orbital and the spin contribution appear separately as constants of motion. There is a difficulty in the understanding of the magnetic properties because, on the contrary Dirac's theory of the hydrogen atom,¹ implies that only the total angular momentum is a constant of motion. Furthermore we have shown that, in a solid, this property is still that of individual electrons which bring their magnetic contribution whatever be the interactions acting on the electron.^{2,3} In this approach the g or Landé factor appears to play a fundamental role, characteristic of the two types of spin states in the same shell. Indeed $g=k/(k+1/2)$ and takes two values in the same shell corresponding to the two types of spin: $g=0.8$ with $k=2$ and $g=1.2$ with $k=-3$ in the $3d$ shell. For example, the experimental magnetic moment of iron is $2.22\mu_B$ where μ_B is the Bohr magneton. In Dirac's model it can arise from the sum of the magnetic contributions of two electrons belonging to the two different types of spin $0.4\mu_B=0.8(1/2)\mu_B$ and $1.80\mu_B=1.2(3/2)\mu_B$ where 0.8 and 1.2 are the corresponding g factors of the two kinds of spin of the $3d$ shell and $1/2$ and $3/2$ are two projections of the

total angular momentum. Similar results are obtained for cobalt, nickel, rare earth metals and chromium compounds and with paramagnetic compounds.^{2,3}

II. THE QUANTUM NUMBERS, THE SPIN AND THE ENERGY

In the first quantum theory the angular and radial motions are characterized respectively by the quantum numbers k and r . The total energy is $E_n=1/2nh\nu$ where ν is the frequency of the periodic motion and n is the total quantum number $n=k+r$. This is obtained from the quantification of the mechanical action with $E_k=1/2kh\nu$ and $E_r=1/2rh\nu$ for the corresponding motions. In Schrödinger's approach we have $n=l+r+1$. The number l replaces k and characterizes the angular momentum, r is still the radial quantum number with the corresponding energy for these two numbers. As a result, the unity in $n=l+r+1$, appears as a special unit of quantification to which corresponds the energy $E_s=1/2h\nu$, but which is not associated to a well defined degree of freedom. We will show that this energy corresponds to the spin motion. In this view let us recall how the doublet energy levels appear in Dirac's theory with $E_{n,k}$ level:

$$\frac{E_{n,k}}{m_0c^2} = \left(1 + \frac{\alpha^2 Z^2}{[p + \sqrt{k^2 - \alpha^2 Z^2}]^2} \right)^{-1/2} - 1. \quad (1)$$

In this expression p and k are two quantum numbers with $n=|k|+p$, the other symbols have their classical meaning. The doublet energy levels characterize two types of solutions:

$$\begin{aligned} \text{Type I: } & k = -l-1 \quad \text{and } p=r; \\ \text{Type II: } & k=l \quad \text{and } p=r+1. \end{aligned} \quad (2)$$

For the two types the energy is almost the same, p characterizes in the wave function $\Psi_{n,k}$ the amount of energy associated with the radial part and $|k|$ the one associated with the angular part. From the study of the solutions the two values $k=-l-1$ and $k=l$ give the same value $l(l+1)$ to the product $k(k+1)$ and form a spin doublet.^{1,4} The relations between p and r result from the study of the correspondence between Dirac's and Schrödinger's solutions. This study shows that the radial functions which enter in the expression of $\Psi_{n,k}$ are very close to each other and they both tend to the Schrödinger wave function.^{1,5}

Thus in Dirac's solutions the energy is characterized by the total quantum number n with the relations $n = |k| + p$ and $n = l + r + 1$. The number l characterizes the orbital angular momentum and the corresponding energy. On the other hand r characterizes the radial motion and its corresponding energy. Furthermore there is still one special unit of quantification apparently not associated with a degree of freedom. But in this approach this special unit comes either from the angular part for type I or from the radial part for type II of $\Psi_{n,k}$ wave function. Now we know that for the two types the spin is an additional angular momentum $s = 1/2\hbar$. As a result it seems reasonable to suppose that this special unit of quantification characterizes the spin and that the energy associated with it is that of the spin motion.

III. THE WAVE FUNCTION, THE ACTION AND THE g FACTOR

To understand this hypothesis we will consider the electron as a fluid mass^{5,6} and suppose that this fluid is composed of small particles that we call "grains." We also suppose that the electromagnetic field is made of the same "grains." Thus along its trajectory the electron receives energy which could be formed of these "grains" from the field but as it cannot continuously accumulate energy it also emits the same amount to keep the balance and in order to have a stable state. This is a possible explanation of the principle of the least action. This picture allows, to understand the wave function as a quantification of the mechanical action.⁷ Indeed, when we search for the solutions of Dirac's equation we try a function which has the spherical symmetry of the electrical field but which is not the one of the trajectory. Now when the field acts on the electron, as a result of its fluidity, there is dispersion which continuously modifies the momenta. As a result the law of conservation of these momenta is deeply modified and indeed we know from Dirac's theory that just the total angular momentum is a constant of motion. In the Sommerfeld approach we have the indication that the wave function is the quantification of the action. We know that before Dirac, he has found the formula of the energy (1) by introducing the relativistic change of the mass along the orbital motion. In doing so one quantifies the action along the trajectory.⁸⁻¹⁰ But Sommerfeld worked with an electron as a material point before the discovery of the spin property. As a result there was no way to recognize that one unit of quantification has to be attributed to the own rotation and that this unit can be taken either from angular or radial part of the action. With this hypothesis we can understand that Sommerfeld finds the same relation as Dirac for the energy of the state.

There is another support to this approach in the magnetic contribution of a given quantum state. Let us first consider the spin contribution to the total angular momentum. When the energy associated with the spin is taken from the angular action, the spin contribution reduces the possible angular momentum $|k|\hbar$ and this is the reason for the negative sign of k . On the contrary, when this energy is taken from the radial action the spin contribution is added to the possible angular momentum $k\hbar$. As a result, the total angular momentum for the two types is $M = |k + 1/2|\hbar$ taking into account

the algebraic sign of k . This is different from the hypothesis that the spin contribution must be added to l in \hbar units giving $j = l + 1/2$ or $j = l - 1/2$. In fact they are the highest values of the magnetic quantum number of the type I and II, respectively. This can be obtained in calculating the magnetic contribution of an electron in a given quantum state. Let u be the projection in \hbar unit of the angular momentum of the state. In a classical approach its magnetic contribution is: $u_e = u\mu_B$ where μ_B is the Bohr magneton. To establish this relation one has to use the classical expression $\mu_e = IS/c$ giving the magnetic moment of a circular current. In this expression I is the intensity of the current and S the surface of the circle. For the electron with an orbital motion having a period T , one has $I = e/T$. On the other hand the area law satisfied in classical as well in relativistic mechanics expressed upon one period gives the relation $2mS = T_M M$. With $u\hbar$ for the projection of M this leads to $\mu_e = u\mu_B$ if $T = T_M$. But the corresponding action of the total angular momentum $M = |k + 1/2|\hbar$ is equal to $|k|\hbar$. As a result the periods T and T_M are different. The period T_M is indeed fictitious and there are the relations:

$$2mS = T|k|\hbar = T_M|k + 1/2|\hbar$$

so that

$$T_M = gT \quad \text{with} \quad g = k(k + 1/2). \quad (3)$$

As a result, the magnetic moment corresponding to u the projection of $M = |k + 1/2|\hbar$ must be multiplied by g , that is $\mu_e = g u \mu_B$ where the Landé factor g is given by 3. This factor as a function of k was first calculated by Dirac⁴ and its role in the magnetic contribution of the electrons is well established in the calculation of the magnetic moment of the atoms^{2,3} and in the interpretation of the Zeeman effect through Runge's law.⁹

IV. WAVE FUNCTION AND TRAJECTORY

The interpretation of the g factor is based upon the hypothesis of a trajectory for the electron. Let us show that with a fluid electron it is possible to describe Dirac's equation as the exchanges of grains between the electron and the field along the trajectory. These exchanges of grains correspond to an amount of energy, mass, momenta and displacement. To satisfy the quantification we suppose that the exchanges of grains are such that: "the characteristic energy of a state must be exchanged on a section of trajectory having a length λ of the wave during the time T of the period associated to λ in such a way that at each time if p is the momentum one has $ET = p\lambda = h$."

Starting with the momentum parallel to the x axis, the exchanges of grains transform a part p_x of this momentum in $\pm p_y$ and $\pm p_z$. The amount of these exchanges is proportional to the cross section σ of the electron, to the velocity c of the light and to the interval of time dt ; that is: $dv = \sigma c dt$. It can be described with $h\Psi_a \sigma c dt$ and Ψ_a can be divided into two components Ψ_3 and Ψ_4 . Let us consider that this exchange of grains leading to a modification of the position of the electron is an absorption. To counterbalance this absorption it must have an emission $h\Psi_e \sigma c dt$ and Ψ_e can be divided into two components Ψ_1 and Ψ_2 .

Let us then consider Dirac's equation:

$$i[(W+eV)/c+m_0c]\Psi_1 dv = (P_x+iP_y)h\Psi_4 dv + P_z h\Psi_3 dv, \quad (D1)$$

$$i[(W+eV)/c+m_0c]\Psi_2 dv = (P_x-iP_y)h\Psi_3 dv - P_z h\Psi_4 dv, \quad (D2)$$

$$i[(W+eV)/c+m_0c]\Psi_3 dv = (P_x+iP_y)h\Psi_2 dv + P_z h\Psi_1 dv, \quad (D3)$$

$$i[(W+eV)/c+m_0c]\Psi_4 dv = (P_x+iP_y)h\Psi_1 dv - P_z h\Psi_2 dv, \quad (D4)$$

according to de Broglie presentation.¹⁰ In this equation P_x stands for $\partial/\partial x$ and so on.

To put in view the amount of emitted or absorbed grains we have multiplied the wave components by $dv = \sigma c dt$. In the equations (D1) and (D2) $(P_x+iP_y)\Psi_4 dv$ and $(P_x-iP_y)\Psi_3 dv$ represent two opposite rotations parallel to the x, y plane. With these two rotations one will recognize a part of the Pauli hypothesis: a wave component for each spin state, but it is the difference of these two rotations which gives the real rotation of the electron. On the other hand $P_z\Psi_3 dv$ and $-P_z\Psi_4 dv$ represent two opposite translations parallel to the z axis. The trajectory is the result of these opposite motion. Let us remark that in the equation (D1):

$$i[(W+eV)/c+m_0c]\Psi_1 dv = i[(W+eV)+m_0c^2]\Psi_1 \sigma dt,$$

where $(W+eV)\Psi_1 \sigma dt$ represents an emission of energy proportional to the difference of density of grains between the electron and the field. On the other hand $m_0c^2\Psi_1 \sigma dt$ represents an emission proportional to the energy of the rest mass of the electron that is the condition to keep the rest mass constant. As a result the first equation appears as an equilibrium between the absorption for one way of variation of momentum and on the other hand the corresponding emission to keep the energy and mass constant. The second equation corresponds to opposite way of variation of momentum.

Finally variations of momentum induce variations of energy of motion. Reciprocally, variation of energy of motion induce variations of momentum. The role of the third and fourth equations is to satisfy this aspect of the motion.

V. CONCLUSION

When we undertook this work our purpose was to get the core of the notion of "spin." For this purpose we have introduced the hypothesis of an electron as a fluid mass made of grains as the electric field and the photon. With this hypothesis it appears then possible to find the equation of Dirac starting from the motion of the electron and as a result to propose a new perception of the wave corpuscle duality. In this view it was essential to recognize the reality of the electronic trajectories as one can do it with the chemical bond or as a consequence of the magnetic properties of the electron. To conduct this work we have used a law of quantification that we can express like this: "the characteristic energy of a state must be exchanged on a section of trajectory having a length λ of the wave during the time T of the period associated to λ in such a way that at each time if p is the momentum one has $ET = p\lambda = h$." Thus this characteristic energy of the occupied quantum state is nothing other than Planck's constant along a wave length and during the associated period. This property arises from the fact that there is no exchange of energy without duration and length. But this constant of action h does not vary with the medium that is of the complexity of the atom, of the molecule or still of the solid, liquid or gas state of the matter in which the electron moves. Thus we understand that the quantum numbers which characterize the quantum state subsist whatever be the situation of the atom. It is that which allows to understand the structure of the periodic table which synthesizes so many chemical and physical properties of the matter. We also understand that the total angular momentum is always the same whatever be the complexity of the atom to which belongs the electron and the medium to which belongs the atom, a property which had remained mysterious.^{1,2}

Aharonov–Bohm oscillations at finite temperature

P. Schlottmann

Department of Physics, Florida State University, Tallahassee, Florida 32306

A. A. Zvyagin

B. I. Verkin Institute for Low Temperature Physics and Engineering of the Ukrainian Academy of Sciences, 47 Lenin Avenue, Kharkov 310164, Ukraine

The Aharonov–Bohm effect is the quantum interference of charged particles in mesoscopic rings enclosing a magnetic field. The wavefunction acquires a phase due to the field flux ϕ and gives rise to flux-dependent oscillations in persistent charge currents. The period and amplitude of the oscillations are associated with the properties of the Fermi surface of the elementary excitations. For systems with one Fermi surface the groundstate persistent current has the form of a saw-tooth. The temperature reduces the amplitudes of oscillation by smearing the Fermi surface. The amplitude of higher harmonics decreases faster with T than the fundamental one, changing the saw-tooth to a more sinusoidal form with much smaller amplitude. The controlling parameter is LT/zv_F , where L is the length of the ring, v_F is the Fermi velocity and z the dressed generalized charge. Our calculations are performed within the framework of Bethe's ansatz. © 1996 American Institute of Physics. [S0021-8979(96)73908-2]

The exact solution of numerous 1D models by means of Bethe's ansatz and the quantum inverse scattering method in conjunction with field-theoretical treatments provided deep insight into the ground state properties, classification of states, thermodynamics, and the asymptotic behavior of correlation functions.

Finite size effects, i.e., the finite length of a conducting or magnetic ring, can manifest itself in several ways: (i) The contribution of impurities to extensive quantities (e.g., the energy) can become large and observable in mesoscopic systems. (ii) The finite length of a ring gives rise to quantum topological effects, i.e., to persistent currents with oscillation periods given by interference patterns of the Aharonov–Bohm (AB)¹ and Aharonov–Casher (AC)² type. (iii) Finite size corrections to the energy determine the critical exponents of the asymptotic dependence at long-distances of correlation functions via conformal field theory.^{3–5}

In the AB effect¹ the wave function of charged particles along a ring picks up a phase proportional to the enclosed magnetic field flux. Dual to the AB effect is the AC² in which the wave function of particles with a magnetic moment acquires a phase due to a radial electric field caused by a straight charged line enclosed by the ring. The quantization of the flux or the phase (modulo 2π) leads to periodic oscillations of the current.⁶ Persistent currents have been observed experimentally in small metal and semiconductor rings.⁷

Persistent currents in interacting systems were studied theoretically with the exact Bethe ansatz method⁸ and the bosonization technique.⁹ The system responds to a magnetic flux by virtually creating and annihilating states at the left and right Fermi points of the Dirac sea. The change of the energy with the flux is on a mesoscopic scale, L^{-1} , if the states are gapless, where L is the length of the ring.

In this paper we present a theoretical study of the AB oscillations in a ring of interacting charged spinless particles. We first state the Bethe ansatz solution for a general integrable model and the finite size corrections to the ground-

state energy. Then we formulate the persistent currents for finite temperatures. The oscillations are strongly suppressed with temperature due to the incoherence introduced by the smearing of the Fermi surface. AB oscillations at finite T were studied previously by bosonizing spinless fermions.⁹ We discuss the limitations of this procedure and the differences with our exact formulation. Finally, we present examples and a brief summary of our results.

We consider N spinless bosons or fermions in 1D interacting via a potential $V(x)$

$$H = - \sum_{j=1}^N \frac{\partial^2}{\partial x_j^2} + \sum_{i < j} V(|x_i - x_j|). \quad (1)$$

We restrict ourselves to potentials that do not lead to bound-states and systems that are integrable. The model can then be solved by means of the asymptotic Bethe ansatz,¹⁰ which expresses the many-body energy eigenvalues in terms of the two-particle phase-shift without explicit knowledge of the manybody wave functions. The application of the asymptotic Bethe ansatz requires an independent proof that the model is integrable. If the model is integrable it suffices to know the asymptotic behavior of the incoming and outgoing wavefunction at long distances, i.e., the scattering phase shift.

The asymptotic two-body wave function for $x_1 \ll x_2$ is

$$\begin{aligned} \psi(x_1, x_2) = & \exp[i(k_1 x_1 + k_2 x_2)] \\ & \pm \exp[i(k_2 x_1 + k_1 x_2) + i\theta(k_1 - k_2)], \end{aligned} \quad (2)$$

while for $x_1 \gg x_2$ we have $\psi(x_1 \gg x_2) = \pm \psi(x_1 \ll x_2)$ for bosons and fermions, respectively. With $k = k_1 - k_2$, k_j being the wave numbers, the scattering matrix is $S(k) = -\exp[-i\theta(k)]$ and $\theta(k)$ is twice the two-body phase-shift. $\theta(k)$ is an odd function of k and the energy is $E = k_1^2 + k_2^2$.

For an integrable model the N -particle scattering matrix asymptotically for large distances between the particles factorizes into a product of $(N-1)$ two-particle scattering matrices. Imposing twisted boundary conditions we obtain¹⁰

$$e^{-i(kL-2\pi\alpha)} = \prod_{q \neq k} S^{-1}(k, q) = (-1)^{N-1} \times \exp \left[i \sum_{q \neq k} \theta(q-k) \right], \quad (3)$$

and after taking the logarithm we have

$$kL = 2\pi(I_k + \alpha) + \sum_{q \neq k} \theta(k-q), \quad (4)$$

where $\alpha = \phi/\phi_0$ with ϕ being the magnetic flux through the ring and $\phi_0 = hc/e$ the elemental magnetic flux quantum. The wave functions are only linearly independent if all rapidities k are different (the rapidities obey Fermi statistics). In the ground state the I_k are different consecutive integers (half-integers) if N is odd (even), $I_{\min} \leq I_k \leq I_{\max}$. The energy is given by $E = \sum_{j=1}^N k_j^2$. Note that Eq. (4) is invariant under the replacement of α by its fractional part to the nearest I_k , $\{\alpha\}$.

In the thermodynamic limit we introduce distribution densities for the rapidities $\rho(k)$ and "holes" $\rho_h(k)$. For the ground state Eq. (4) reduces to the following integral equation

$$\rho_h(k) + \rho(k) + \int_{-Q}^Q (dq/2\pi) \rho(q) \theta'(k-q) = 1/(2\pi) \quad (5)$$

with $\theta'(k) = d\theta(k)/dk$. The ground state energy and the number of particles are

$$E_\infty = L \int_{-Q}^Q dk k^2 \rho(k), \quad N/L = \int_{-Q}^Q dk \rho(k). \quad (6)$$

We define an energy band as $\epsilon(k) = \lim_{T \rightarrow 0} T \ln[\rho_h(k)/\rho(k)]$, which satisfies

$$\epsilon(k) = k^2 - \mu + \int_{-Q}^Q dq \epsilon(q) \theta'(k-q), \quad (7)$$

where μ is the chemical potential. According to the Fermi statistics obeyed by the rapidities, states with negative ϵ are occupied (particles), while states with positive energy potential are empty (holes). The zeroes of ϵ , i.e., $\epsilon(\pm Q) = 0$ define the Fermi surface and also relate the integration limit Q to μ .

A particle (hole) excitation is introduced into the Fermi sea by adding (removing) a rapidity to (from) the set $\{k\}$. The energy and momentum of the excitations is given by

$$\mathcal{E}_{\text{exc}}(k) = |\epsilon(k)|, \quad p(k) = 2\pi \int_0^k dq [\rho_h(q) + \rho(q)]. \quad (8)$$

Excitations with $|k| < Q$ correspond to holes, while $|k| > Q$ parametrizes particles. The excitation energy vanishes at the Fermi level, $k = \pm Q$. The Fermi momentum is then $p_F = \pi N/L$. The linear superposition principle holds for any finite number of excitations.

Close to the Fermi points the energy dispersion (8) is proportional to the momentum, $\mathcal{E}_{\text{exc}}(p) = v_F(|p| - p_F)$, with the Fermi velocity given by

$$v_F = |\partial \epsilon(k)/\partial k|_{k=Q} [2\pi \rho(Q)]^{-1}. \quad (9)$$

The corrections to the energy due to the finite length of the ring can be calculated following the procedure developed in Refs. 3 and 11. The change of the energy, $\Delta E(\alpha)$, associated with the magnetic field flux is

$$\Delta E(\alpha) = (2\pi v_F/L) ([z(D + \{\alpha\})]^2 - 1/12), \quad (10)$$

where $2D = I_{\max} + I_{\min}$ is a number determined mod(1) that gives the initial phase shifts or parity of the level crossing. The quantity z is the dressed generalized charge at the Fermi points, $z = \xi(k=Q)$, determined by

$$\xi(k) = 1 - \int_{-Q}^Q dq \xi(q) \theta'(k-q). \quad (11)$$

Note that for particles with parabolic dispersion, as in Eq. (1), $\xi(k) = 2\pi(\rho_h(k) + \rho(k))$. According to Eq. (10) the ground state energy is a parabolic periodic function of the magnetic flux.

To study the temperature dependence of the oscillations we write the free energy as

$$F = E_\infty + \Delta E(\alpha) + \Delta F(T),$$

$$\Delta F(T) = -(TL/2\pi)$$

$$\times \int dp \ln \{1 + \exp[-\mathcal{E}_{\text{exc}}(p, \alpha)/T]\}, \quad (12)$$

where $\Delta F(T)$ is the thermal population of the particle and hole excitations according to the Fermi statistics of the rapidities. $\Delta F(T)$ vanishes as $T \rightarrow 0$. The expression for $\Delta F(T)$ is valid only for low temperatures, since we neglect the change of the spectrum with T .

We are interested in the finite size corrections associated with the magnetic flux contained in $\Delta F(T)$. The dimensionless parameter controlling the amplitude is zv_F/LT , i.e., the range of T over which the oscillations are observable decreases with L . For low-energy excitations we use the linearized dispersion about the Fermi points at $\pm p_F$. Both Fermi points contribute equally. For excitations about the Fermi point at $+p_F$ we have

$$p - p_F = 2\pi \rho(Q)(k - Q) = 2\pi z(I - I_{\max} + D + \{\alpha\})/L, \quad (13)$$

where $(I - I_{\max})$ is an integer, D is zero (1/2) if N is odd (even), and we introduced the phase-shift α due to the magnetic flux. The integral over the physical momentum is now replaced by a sum over integers I

$$\Delta F(T) = -2Tz \sum_{I=-\infty}^{\infty} \ln[1 + \exp(-zv_F 2\pi |I + \{\alpha\}|/LT)], \quad (14)$$

where D has been absorbed into α and the sum has been extended to infinity since the exponential converges fast. Using Poisson's formula we obtain

$$\begin{aligned} \Delta F(T) = & -(zTL/\pi) \int_{-\infty}^{\infty} dx \ln[1 + \exp(-zv_F |x|/T)] \\ & - (2zTL/\pi) \sum_{s=1}^{\infty} (-1)^s \cos(2\pi \alpha s) \\ & \times \int_{-\infty}^{\infty} dx \cos(Lxs) \ln[1 + \exp(-zv_F |x|/T)], \end{aligned} \quad (15)$$

where the symmetry of the excitation spectrum about p_F has been used. The first term is extensive and nonoscillatory; it gives rise, e.g., to the low- T specific heat $C/L = (\pi T/3v_F)$.

Two partial integrations of the oscillatory terms yield

$$\Delta F_{\text{osc}}(T) = -(2z^2 v_F / \pi L) \sum_{s=1}^{\infty} (-1)^s s^{-2} \cos(2\pi \alpha s) \times \left(1 - (zv_F/4T) \int_{-\infty}^{\infty} dx \cos(Lxs) \times \cosh^{-2}(zv_F|x|/2T) \right). \quad (16)$$

The sum of the first term and the integral in the second term can be evaluated yielding

$$\Delta F_{\text{osc}}(T) = -(2\pi z^2 v_F / L) [\{\alpha\}^2 - 1/12] + 2zT \times \sum_{s=1}^{\infty} (-1)^s s^{-1} \cos(2\pi \alpha s) \sinh^{-1}(\pi L s T / zv_F). \quad (17)$$

As $T \rightarrow 0$ the two terms in Eq. (17) cancel each other. The effect of parity is incorporated by replacing $\{\alpha\}$ by $(\{\alpha\} + D)$.

Collecting all finite size effects from (10), (12), and (17) we obtain

$$F_{\text{osc}} = \frac{\pi v_F}{6L} [z^2 - 1] + 2zT \sum_{s=1}^{\infty} \frac{(-1)^{N_s}}{s} \frac{\cos(2\pi \alpha s)}{\sinh(\pi L s T / zv_F)}. \quad (18)$$

The first term is a constant finite size correction and not relevant to the persistent current. The parity effect is now explicitly contained. The persistent current is the derivative of F with respect to the flux.

We have calculated the finite size corrections for a gas of spinless interacting particles at finite T . Charged particles couple to the magnetic field flux enclosed by the ring, giving rise to an AB quantum interference and persistent current. As a function of the magnetic field the persistent current oscillates with the periodicity of the elemental flux quantum. At $T=0$ the current has a saw-tooth shape, which is changed to a more sinusoidal pattern (with the same periodicity but strongly reduced amplitude) at finite T . The controlling dimensionless parameter is (LT/zv_F) . T suppresses the higher harmonic content, as a consequence of the smearing of the Fermi surface. The physical picture is the same as in the de Haas-van Alphen effect, where T introduces incoherence in the wave function while a particle completes its closed orbit.

We have restricted our calculation to integrable systems with only one Fermi surface and to potentials that do not lead to boundstates (no string solutions of the Bethe ansatz equations). We believe that our results are a generic feature of 1D systems valid independently of the integrability. In particular, any one-component Luttinger liquid should exhibit this behavior. Using the bosonization of fermions Loss⁹ calculated the T -dependence of the persistent AB current for spinless charged fermions with nearest neighbor interaction

$$H = - \sum_i (c_i^\dagger c_{i+1} + c_{i+1}^\dagger c_i) + U \sum_i c_i^\dagger c_i c_{i+1}^\dagger c_{i+1}. \quad (19)$$

The bosonization neglects the natural cutoffs of the model, i.e., of the tight-binding band and the interaction. Results are therefore restricted to small coupling strengths. The bosonization is strictly valid only in the thermodynamic limit; this may cause some ambiguities in the extraction of finite size effects. Expectedly Loss' results⁹ differ from our exact ones in the dressing of the quantities (selfenergy effects).¹²

A few integrable models for which our results are exact are the following (listed are the potentials and the function θ): (i) For charged bosons interacting via the potential $V(x) = 2c\delta(x)$ the phase-shift is $\theta(k) = -2 \tan^{-1}(k/c)$,¹³ (ii) for spinless particles interacting via the potential $V(x) = g(\pi/L)^2 \sin^2(\pi x/L)$ we have $\theta(k) = (\pi/2) \text{sgn}(k) [(1+2g)^{1/2} - 1]$,¹⁰ (iii) for particles interacting via $V(x) = 2\lambda(\lambda+1) \sinh^{-2}(x)$ the $\theta(k)$ is¹⁰

$$\theta(k) = 2i \text{Im} \ln[\Gamma(1+ik)/\Gamma(1+\lambda+ik)], \quad (20)$$

and (iv) for a potential of the Toda-type $V(x) = (\omega^2/2\gamma^2) \{\exp[-\gamma(|x|-x_0)] + \gamma(|x|-x_0) - 1\}$, where γ controls the anharmonicity and x_0 is a hard-sphere radius,¹⁴

$$\theta(k) = k(x_0 + (2/\gamma) \ln(\omega/2\gamma^2) + 2i \text{Im} \ln[\Gamma(1+ik/\gamma)]). \quad (21)$$

With minor modifications to Eqs. (5)–(7) our results are also valid for lattice models, for example (v) the model (19), which can be mapped onto the XXZ-Heisenberg chain via a Wigner-Jordan transformation,¹⁵ and (vi) the Hubbard model with attractive U .¹⁶ In the Hubbard model the electrons form singlet boundstates of the Cooper-pair-type which have a Fermi surface and are the particles displaying the persistent current. Gaps prevent the population of all other excitations at low T .

Study of the frequency dependence of the ferromagnetic resonance linewidths of nickel ferrites from 8–60 GHz

L. Torres, M. Zazo, A. G. Flores, V. Raposo, and J. Iñiguez

Departamento de Física Aplicada, Universidad de Salamanca, E-37071 Salamanca, Spain

In this communication we present in a systematic way experimental data on ferromagnetic resonance (FMR) linewidths of polycrystalline nickel ferrites ($\text{Ni}_x\text{Fe}_{3-x}\text{O}_4$ with $0.8 < x < 1.5$) from 8 to 12.4 GHz and from 26.5 to 60 GHz. Data from 26.5 to 60 GHz were taken at room temperature while measurements at X band have been carried out from 77 to 400 K. Neither in X band nor from 26.5 to 60 GHz was a clear frequency dependence found. Classical contributions to the FMR linewidth according to Sparks' outline are analyzed in the whole range of frequencies from 8 to 60 GHz. Contributions of the porosity, anisotropy, slowly and rapidly relaxing impurities, valence exchange and eddy current mechanisms are considered. © 1996 American Institute of Physics. [S0021-8979(96)29708-2]

I. INTRODUCTION

Part of our work in the last years has been devoted to the study of nickel ferrites. Our research has mainly dealt with magnetic disaccommodation and ferromagnetic resonance (FMR) processes. In magnetic disaccommodation, experiments have always been performed at 1 kHz¹ while in FMR we have worked in X band,² $K\alpha$ (26.5–40 GHz) and U (40–60 GHz) bands.³ We have handled both single and polycrystalline nickel ferrites and lately we have also found new relationships between disaccommodation and FMR measurements⁴ using an induced anisotropy formalism.

In this article we present a study of the frequency dependence of the linewidth joining our results from 8 to 60 GHz. As is well known, nickel ferrites are used by technology in several fields and together with Mn and Zn ferrites they are the basis for more complicated compositions. For instance, nickel ferrites partially substituted by zinc are one of the most used compositions in commercial microwave materials.⁵ Therefore, our study of the dependence of the linewidth with frequency and temperature for nickel ferrites in such a wide range offers interesting information about relaxation processes in FMR which could be very useful in order to minimize the losses in technical applications.

II. EXPERIMENT

Nickel ferrite samples $\text{Ni}_x\text{Fe}_{3-x}\text{O}_4$ with $0.8 < x < 1.5$ were prepared following the ceramic method by sintering intimate mixtures of the appropriate high-purity oxides. Sintering was performed at 1400 °C during 24 h in oxygen atmosphere. As is usual, at the end of the process the samples were rapidly quenched in liquid nitrogen. In order to carry out FMR measurements, the samples were spherically shaped with a diameter between 0.6 and 0.7 mm. The surface was polished with diamond paste of 6 μm so that the diameter of the pits is of this magnitude.⁶

Two different experimental techniques have been used for measuring FMR. At X band a standard SMA coaxial

transmission line has been chosen in order to facilitate the implementation of the system in a conventional cryostat. From 26.5 to 60 GHz a waveguide setup was required because at these frequencies the losses in transmission lines are too large.

In both cases the measurement was accomplished by monitoring the reflected wave in a short circuit. The linewidth is obtained by sweeping the static magnetic field around the resonance situation for each temperature and storing in the computer the relative reflected power. As is well known, this microwave absorption is proportional to the imaginary part χ'' of the diagonal component χ_e of the external susceptibility tensor $\underline{\chi}_e$ (Ref. 6) and the linewidth ΔH is defined as the mid-height width of the curve χ'' vs H (static magnetic field). The linewidths ΔH presented here are calculated, according to this classical definition, fitting the experimental points by means of a nonlinear computational technique.

At X band, the temperature of the cryostat chamber is controlled by an intelligent temperature controller with a stability better than 0.1 K. An additional platinum resistance located outside the short circuit at a distance of 2 mm from the sample registers its temperature. The whole process is automated so that the dependence with the temperature of FMR linewidth can be obtained in a few hours.²

At $K\alpha$ and U bands, most of measurements were performed at room temperature although some measurements at liquid nitrogen temperature could be done at $K\alpha$ band.³

III. RESULTS

Measurements at room temperature were carried out for all compositions from 8 to 12.4 GHz but no clear dependence of the linewidth appears in this range for most of the samples. In Fig. 1 measurements from 77 to 350 K for $\text{Ni}_{0.8}\text{Fe}_{2.2}\text{O}_4$ at several frequencies can be observed. It seems that there is a slight increase in the linewidth with frequency but we should take into account that the experimental error is

FIG. 1. FMR linewidths from 77 to 350 K for $\text{Ni}_{0.8}\text{Fe}_{2.2}\text{O}_4$ at 8.5, 10, 11, and 12 GHz.

around 7% (as is typical for FMR experiments^{2,3,6}) and that the maximum change in the linewidth with frequency is of 10%. Then we cannot affirm that there is a clear increase in the linewidth with frequency.

In Fig. 2 we show the linewidths for the different compositions measured at 11 GHz from 77 to 350 K. The dependence of the linewidths with temperature provides information about the relaxation processes present in the samples and it will be useful for the study of the frequency dependence, as will be shown in the Discussion.

FMR from 26.5 to 60 GHz was measured in detail at room temperature and no clear dependence in the linewidth came into view.³ The value of the average linewidth for all the samples at these frequencies was clearly larger than the one found at X band. In Fig. 3, the linewidth for the different compositions measured at 11 and 30.5 GHz can be seen. In the same graph we present the data for liquid nitrogen and room temperature.

FIG. 2. FMR linewidths from 77 to 350 K at 11 GHz for $\text{Ni}_x\text{Fe}_{3-x}\text{O}_4$ with $0.8 < x < 1.5$.

FIG. 3. FMR linewidths for $\text{Ni}_x\text{Fe}_{3-x}\text{O}_4$ with $0.8 < x < 1.5$ measured at 11 and 30.5 GHz at 77 and 298 K.

IV. DISCUSSION

From measurements carried out in such a wide range of frequencies some aspects are worth noting:

- (1) For all the compositions linewidths are not clearly frequency dependent either in the X band or from 26.5 to 60 GHz. On the other hand, there is a clear difference between the average values of the linewidths in the X band and the average values from 26.5 to 60 GHz.
- (2) The variation of the linewidth with composition is similar for the X band and $K\alpha$ and U bands with the lowest linewidths being always found for $\text{Ni}_1\text{Fe}_2\text{O}_4$. However, at room temperature, in X band the largest linewidths are found for $\text{Ni}_x\text{Fe}_{3-x}\text{O}_4$ with $x > 1$ while at $K\alpha$ and U bands the largest ones are found for $\text{Ni}_x\text{Fe}_{3-x}\text{O}_4$ with $x < 1$.

In order to understand these aspects, the contributions to the linewidth in polycrystalline samples have to be analyzed. The total linewidth for a polycrystalline ferrite is⁶

$$\Delta H = \Delta H_p + \Delta H_a + \Delta H_s, \quad (1)$$

where ΔH_p is the contribution induced by the porosity, ΔH_a is the broadening due to the random orientation of the anisotropy axes of the different crystallites of the polycrystal, and ΔH_s is the linewidth of the single crystal.

ΔH_s should include the following contributions: intrinsic contribution of Kasuya-Le Craw type,⁶ surface roughness, valence exchange, slowly relaxing impurities, and rapidly relaxing impurities.⁶ From these contributions we will not consider the intrinsic and the surface ones because their magnitude is negligible when we are dealing with polycrystalline linewidths of some hundred of oersted. Besides, we will not consider the rapidly relaxing impurities contribution because it should exhibit a linear dependence with frequency which has not been observed in our measurements.

In this way, ΔH_s will include valence exchange and slowly relaxing impurity mechanisms. The latter will be present for compositions with $x > 1$ ² while the former will

contribute in compositions with $x < 1$ in which the presence of Fe^{2+} ions gives rise to a valence exchange mechanism between Fe^{2+} – Fe^{3+} .

The contribution of porosity takes the form⁶

$$\Delta H_p = \frac{8\pi}{45} 4\pi M_s \frac{1}{\cos \theta_u} \frac{V_{\text{pits}}}{V} \left(1 - \frac{V_{\text{pits}}}{V} \right), \quad (2)$$

where V_{pits} is the volume of the pores in the sample, V the total volume of the sample, M_s is the saturation magnetization, and θ_u is the angle between the internal magnetic field and the wave vector k of the spin waves. For $k=0$, $\omega_k = \omega_u = \omega_0 = \gamma H_0$ we find⁶

$$\cos^2 \theta_u = \frac{1}{3} \left(\frac{3-2\alpha}{3-\alpha} \right); \quad \alpha = \frac{4\pi M_s}{H_0}, \quad (3)$$

where H_0 is the resonance field.

According to Schlöman's calculations,⁷ the anisotropy contribution can be written as

$$\Delta H_a = 2.07 \frac{H_a^2}{4\pi M_s} \left[\frac{\Omega + \frac{1}{3} + 19\Omega/360}{\sqrt{\Omega(\Omega - \frac{1}{3})}} \right], \quad (4)$$

with

$$\Omega = \frac{f}{\gamma 4\pi M_s} - \frac{1}{3}, \quad H_a = -\frac{2k_1}{M_s}, \quad (5)$$

where γ is the gyromagnetic ratio and k_1 is the first-order anisotropy constant, H_a being the anisotropy field.

The peak processes contribution (valence exchange or slowly relaxing) can be expressed as⁶

$$\Delta H = C \frac{\omega \tau_r}{1 + (\omega \tau_r)^2}, \quad (6)$$

where C is a constant and τ_r is the relaxation time of the corresponding process which can be expressed as⁶

$$\tau_r = \tau_0 \exp \frac{Q}{kT}, \quad (7)$$

where Q is the activation energy and τ_0 is a pre-exponential time factor.

For the composition $\text{Ni}_1\text{Fe}_2\text{O}_4$, at room temperature, a study of the frequency dependence of the different contributions to the linewidth has been carried out. The contributions given by Eqs. (2), (4), and (6) have been computed considering the theoretical values of $M_s = 270$ Oe,⁸ $k_1 = -620$ 00 erg/cm³⁸ and the effective Lande factor, $g_{ef} = 2.19$.⁸ We have also considered the experimental values of porosity ($V_{\text{pits}}/V = 0.06$)⁹ and the resonance field. Besides we have taken $\tau_0 = 3 \times 10^{-13}$ s and $Q = 0.06$ eV, as measured in hopping processes.¹⁰

The best fitting for X band is obtained for $C = 1000$ Oe [see Eq. (6)]. With this value of C , X band data are correctly fitted but some deviations appear in $K\alpha$ and U bands where theoretical linewidths are lower than the experimental ones. Although this kind of analysis is not very accurate, mainly in our ferrites where porosity contribution is important, it is

very useful in order to know which relaxation processes are taking place in these ferrites.

From the study of the results of the fitting it could be thought that the lower theoretical values obtained in $K\alpha$ and U bands are related to an eddy current contribution. The eddy current linewidth was studied by Sparks in the case of infinite skin depth.⁶ He found that this contribution was linear versus the conductivity, increases as the square of frequency and also as the square of sample diameter. Then the eddy current contribution could justify the linewidth at high frequencies where this contribution is more important. However, this elementary assumption would imply an eddy current linewidth which should be proportional to the square of frequency⁶ but this dependence is not observed experimentally.³

Nevertheless, the largest linewidths at high frequencies are found for $\text{Ni}_x\text{Fe}_{3-x}\text{O}_4$ with $x < 1$. For compositions with $x < 1$ hopping between Fe^{2+} – Fe^{3+} produces valence exchange and then eddy current losses can be larger. The fact that at high frequencies samples with $x < 1$ present larger linewidths indicates that there is some kind of eddy current contribution. In spite of that this contribution cannot be proportional to the square of frequency because it has not been observed.

We think that in our samples the eddy current losses are also affected by the decrease of the skin depth, δ , with the increasing frequency, i.e., for $\text{Ni}_{0.8}\text{Fe}_{2.2}\text{O}_4$ $\delta = 1.03$ mm for $f = 8$ GHz and $\delta = 0.37$ mm for $f = 60$ GHz.¹¹ The competition in the eddy current contribution between the increasing frequency and the decreasing skin depth could give rise to the observed experimental linewidths. The eddy current contribution for finite spherical samples in which the skin depth cannot be considered infinite has not been reported. It does not seem easy to calculate mainly because if the skin depth is not infinite a broad spectrum of spin waves could be excited.

Pulsed laser deposition using bulk NiOFe_2O_3 targets onto heated substrates has been used to synthesize single phase Ni spinel ferrite films onto various substrates. Flowing oxygen has been used during the deposition to maintain the oxygen stoichiometry. Ni ferrite films have been deposited onto C-, R-, and A-plane sapphire, polycrystalline Al_2O_3 , and fused silica. Single-crystal (111) oriented NiOFe_2O_3 films have been made onto C-plane sapphire for substrate temperatures of greater than 900 °C. Polycrystalline highly (400) textured Ni ferrite films have been made onto R-plane sapphire with $I(400)/I(311)=6.15$. Films made onto A-plane sapphire, polycrystalline alumina, and fused silica showed only moderate texturing. The coercive force of the (111) oriented NiOFe_2O_3 was 120 Oe perpendicular to the film plane and 95 Oe in plane. © 1996 American Institute of Physics. [S0021-8979(96)29808-9]

I. INTRODUCTION

The development of ferrite films for use in monolithic microwave integrated circuits is an area of active research.¹ Generally most methods of ferrite film preparation require multiple step processing. Pulsed laser deposition is an exception to this since deposition with flowing oxygen onto heated substrates can produce spinel ferrite films without any subsequent heat treatments as first shown for Zn ferrite.² Polycrystalline Ni-Zn-ferrite films were also made onto glass substrates by pulsed laser deposition at relatively low substrate temperatures.³ Pulsed laser deposition oriented Ni ferrite films with certain orientations have been reported for some substrates.⁴ The synthesis of certain ferrite films has been reviewed recently.⁵ Sputtered film growth usually requires a postdeposition heat treatment to develop the spinel ferrite structure.⁶ Preferential (*hhh*) textured spinel films were obtained following postdeposition annealing for ion-beam sputtered films.⁶ In this article we report the synthesis of single step, single phase NiOFe_2O_3 ferrite films prepared by pulsed laser deposition from bulk nickel ferrite targets. Distinctly different crystal textured films have been grown by using different substrates. Single-crystal (111) oriented NiOFe_2O_3 films were grown onto C-plane sapphire substrates as verified by Kikuchi backscattered electron diffraction. Polycrystalline highly (400) textured NiOFe_2O_3 films were grown onto R-plane sapphire substrates. To the best of our knowledge, no other reporting of such fully textured Ni-ferrite films has been found in the literature. It is especially important for optimal applications to utilize films such that the easy direction of magnetization is perpendicular to the film plane. For NiOFe_2O_3 the easy direction of magnetization is along the (111) direction.⁷

II. EXPERIMENT

A Nd-yttrium aluminum garnet (YAG) pulsed laser deposition system located at MARTECH, FSU, has been used to deposit nickel ferrite films onto various heated substrates. The laser wavelength was 1064 nm with 30, 8 ns wide, pulses/s. The pulse energy was 700 mJ with a peak power of 85 MW. The laser beam was directed at 20° from the target normal with a target to substrate distance of 1.5 cm. The laser beam was rastered over the target surface by a computer controlled movable mirror. Different polished substrates have been used including C-plane sapphire, A-plane sapphire, R-plane sapphire, polycrystalline Al_2O_3 , and fused silica. The substrate size was 5 mm×5 mm for sapphire and fused silica, and 50 mm×12.5 mm for the polycrystalline alumina substrates. A flowing O_2 gas pressure of 200 m Torr was used during the deposition for the data presented here. The films were deposited at an average rate of 5 Å/s for 2 h. This allowed relatively thick films to be produced and steady-state deposition conditions to be established. Lower O_2 pressures resulted in films exhibiting α -Fe and impurity phases. Except as noted the samples have not been subjected to any postdeposition heat treatments. X-ray diffraction data have been collected using a diffractometer with Cu $K\alpha$ radiation. The film thicknesses were measured by profilometer with 5 Å resolution. Magnetic measurements have been made using a vibrating-sample magnetometer located at Queens College of CUNY.

III. RESULTS AND DISCUSSION

Single-crystal nickel ferrite, NiOFe_2O_3 , films oriented to have the cubic cell diagonal perpendicular to the substrate plane have been grown by using pulsed laser deposition to deposit the films at relatively high temperatures onto C-plane sapphire substrates. An x-ray diffraction trace of such a fully oriented film grown onto a C-plane sapphire substrate at 930 °C is shown in Fig. 1. Only the NiOFe_2O_3 (111), (222), and (333) family of reflections was evident for the higher

^{a)}Physics Department, Queens College of CUNY, Flushing, New York 11367.

FIG. 1. A x-ray diffractometer trace, Cu $K\alpha$ radiation, for a NiOFe_2O_3 film made onto a 930 °C *C*-plane sapphire substrate is shown. The oxygen pressure during deposition was 200 m Torr. Kikuchi backscattered electron diffraction has been used to show this is a single-crystal film.

substrate temperatures of ≥ 830 °C. The (006) *C*-plane sapphire line at 41.68° is very weak so that there are no competing substrate lines. It was determined that the film of Fig. 1 was single crystal by Kikuchi backscattered electron diffraction.⁸ No rotation of the Kikuchi pattern was observed for this film as the electron beam was scanned across the film. This verified that the film was single crystal. The films on *C*-plane sapphire were ≈ 3.6 μm thick. For lower substrate temperatures the (311) and (400) reflections began to become evident first. For a *C*-plane sapphire substrate temperature during deposition of 625 °C, the (222) reflection was still enhanced but the (311) dominant reflection of the powder pattern dominated.

Nickel ferrite films similarly deposited onto *R*-plane sapphire substrates exhibited predominantly (400) textured growth for the higher substrate temperatures during the deposition. An x-ray diffractometer trace for a NiOFe_2O_3

FIG. 2. An x-ray diffractometer trace, Cu $K\alpha$ radiation, for a NiOFe_2O_3 film made onto a 910 °C *R*-plane sapphire substrate is shown. The oxygen pressure during deposition was 200 m Torr. Substrate lines are indicated by the letter S.

FIG. 3. An x-ray diffractometer trace, Cu $K\alpha$ radiation, for a NiOFe_2O_3 film made onto a 910 °C *A*-plane sapphire substrate is shown. The oxygen pressure during deposition was 200 m Torr. The (110) sapphire line is indicated by the letter S.

film deposited onto *R*-plane sapphire is shown in Fig. 2. Kikuchi backscattered electron diffraction measurements gave no pattern in this case indicating that the films consisted of oriented crystallites with a diameter of less than 1 μm .

In contrast to the extreme textures grown on *C*-plane and *R*-plane sapphire, films grown onto *A*-plane sapphire were not fully textured even at the higher substrate temperatures. An x-ray trace for a NiOFe_2O_3 film grown onto *A*-plane sapphire is shown in Fig. 3. In this the (400) reflection exceeded the (311) intensity which is in contrast to the powder pattern where the (311) dominates the (400) intensity by a factor of 4.

The x-ray lines of the nickel ferrite films grown onto all three sapphire cuts were sharp and distinct for the as-deposited films.

Similar films grown onto fused silica substrates also produced sharp diffraction lines, but strong preferential textur-

FIG. 4. An x-ray diffractometer trace, Cu $K\alpha$ radiation, for a NiOFe_2O_3 film made onto a 650 °C fused silica substrate is shown. The oxygen pressure during deposition was 200 m Torr.

FIG. 5. An x-ray diffractometer trace, Cu $K\alpha$ radiation, for a NiOFe_2O_3 film made onto a 750°C polycrystalline alumina, Al_2O_3 , substrate is shown. The oxygen pressure during deposition was 200 m Torr. The substrate lines are indicated by the letter S.

ing was not evident. In this case the relative x-ray intensities approached those observed in the powder pattern. An x ray for a NiOFe_2O_3 film grown onto a fused silica substrate is shown in Fig. 4. In this case the background has an amorphous hump near 22° from the substrate.

Similarly synthesized nickel ferrite films made onto heated polycrystalline Al_2O_3 substrates exhibited broadened diffraction lines which could only be sharpened to a certain extent by subsequent heat treatments of the films. An x-ray trace showing the broadened lines of NiOFe_2O_3 (311) dominant reflection is shown in Fig. 5. In this case the diffraction lines of the polycrystalline Al_2O_3 substrate dominate the pattern and some impurity phases are present.

Room-temperature magnetic hysteresis loops were measured for the as-deposited films. The (222) NiOFe_2O_3 textured film of Fig. 1 grown onto C-plane sapphire indicated a coercive field of 120 Oe measured perpendicular to the film plane and 95 Oe measured in the plane of the film. The saturation flux density, $4\pi M_s$, was 1.9 kG as deduced from the approach to saturation of the perpendicular magnetization. This method can be used since the demagnetization factor for the perpendicular to the film plane measurements is very close to $N_d = 4\pi$. The easy direction of magnetization is shown to be in the (222) direction as expected. The sample of Fig. 5 grown onto polycrystalline alumina exhibited a coercivity of 150 Oe both perpendicular and parallel to the film plane.

The texture modes grown by using the different substrates are summarized in Table I. The most important results

TABLE I. The dominant NiOFe_2O_3 x-ray texture for different substrates is shown for pulsed laser deposition with 200 m Torr O_2 and high substrate temperatures.

Substrate	Ni-ferrite Dominant texture	$I(400)/I(311)$ Intensity ratio
C-Plane sapphire (006)	(111), (222), (333) only single-crystal films	Neither detected
A-Plane sapphire (110)	(311)	1.20
R-Plane sapphire (012)	(400)	6.15
Fused silica	Random, (311)	0.400
Polycrystalline Al_2O_3	(311) as deposited, after flash heating in air	$I(220)/I(311) = 0.544^a$ $I(220)/I(311) = 0.433^a$

^aFor the polycrystalline Al_2O_3 substrates the intensity ratio for the $I(220)$ reflection is used because of the strong Al_2O_3 (113) peak which is nearly coincident with the NiOFe_2O_3 (400) peak.

of this article are that single-crystal NiOFe_2O_3 films can be grown by pulsed laser deposition with (111) orientation onto C-plane sapphire, and that highly (400) textured polycrystalline NiOFe_2O_3 films can be grown onto R-plane sapphire substrates. Single-crystal (111) oriented NiOFe_2O_3 films exhibit threefold symmetry in the substrate plane and d_{111} exceeds the a lattice parameter of Al_2O_3 by only 1.18%. These conditions allow the growth of single-crystal (111) oriented NiOFe_2O_3 films onto C-plane sapphire. Relatively high substrate temperatures of $\geq 900^\circ\text{C}$ have been required to grow completely oriented and/or textured films. The single-crystal (111) oriented films are of special interest since the easy direction of magnetization for NiOFe_2O_3 is along that direction.

Ni-Co ferrite has been studied with Mössbauer spectroscopy and x-ray diffraction. The crystal structure for this system is spinel, and the lattice constant is in accord with Vegard's law. The Mössbauer spectra consist of two six-line patterns corresponding to Fe^{3+} at the tetrahedral (*A*) and octahedral (*B*) sites. The Néel temperature increases linearly with Ni concentration, suggesting the superexchange interaction for the Ni-O-Fe link is stronger than that for the Co-O-Fe link. It is found that Debye temperatures for the *A* and *B* sites of CoFe_2O_4 and NiFe_2O_4 are found to be $\theta_A = 734$ K, $\theta_B = 248$ K, and $\theta_A = 378$ K, $\theta_B = 357$ K, respectively. The intensity ratio of the *A* to *B* patterns is found to increase at low temperatures with increasing temperature due to the large difference of Debye temperatures of the two sites and to decrease at high temperatures due to migration of Fe^{3+} ions from *A* to *B* sites. Atomic migration of CoFe_2O_4 starts near 400 K and increases rapidly with increasing temperature to such a degree that 69% of the ferric ions as the *A* sites have moved over to the *B* sites by 780 K. It is noted that, as the Ni concentration in cobalt ferrite increases, the Debye temperatures tend to decrease the migration at the *A* and *B* sites is slow.

I. INTRODUCTION

A ferrimagnetic spinel can be represented by the formula AB_2O_4 , the *A*-*B* magnetic interactions between the magnetic atoms on the *A* (tetrahedral) sites and the magnetic atoms on the *B* (octahedral) sites are stronger than the *A*-*A* and *B*-*B* interactions.¹ Metallic atoms of a ferrimagnetic spinel are in an inverse distribution; half the atoms of iron are in the *A* sites and the other half plus magnetic atoms in the *B* sites. However, CoFe_2O_4 ^{2,3} is not completely inverse, and the degree of inversion depends on the heat treatment. The area ratio, $\text{Fe}(A)/\text{Fe}(B)$, has been found to vary from 0.61 ± 0.04 to 0.87 ± 0.04 for two extreme quenched and slowly cooled CoFe_2O_4 samples, respectively. NiFe_2O_4 is an inverse spinel. Chappert and Frankel⁴ have shown that the spin arrangement in NiFe_2O_4 is of the Néel collinear type. The ferrimagnetic Néel temperature was found to be 868 K by the thermal scanning technique.⁵

In this article, we present our Mössbauer and x-ray results on slowly cooled $\text{Ni}_x\text{Co}_{1-x}\text{Fe}_2\text{O}_4$ with special emphasis on atomic migration as a function of temperature and on the Debye temperature for *A* and *B* sites.

II. EXPERIMENT

The slowly cooled $\text{Ni}_x\text{Co}_{1-x}\text{Fe}_2\text{O}_4$ samples were prepared by direct reaction of elements in an evacuated quartz tube. The starting materials were high-purity Fe_2O_3 (99.995%), NiO (99.999%), and CoO (99.999%). Mixtures of the elements in the proper proportions were sealed in evacuated quartz ampoules, heated at 1000 °C for two days, and then slowly cooled to room temperature at a rate of 10 °C/h. In order to obtain a homogeneous material, it was necessary to grind the samples after the first firing and to press the powders into pellets before annealing then for a second time in evacuated and sealed quartz ampoules. The Mössbauer spectra were recorded using a conventional Mössbauer spectrometer of the electromechanical type⁶ with a 10 mCi ^{57}Co source in a Rh matrix.

III. RESULTS

X-ray diffraction patterns of the $\text{Ni}_x\text{Co}_{1-x}\text{Fe}_2\text{O}_4$ were obtained in the θ - 2θ geometry with $\text{Cu } K_\alpha$ radiation. The lattice constant a_0 for each composition was found by plotting $a(\theta)$ against the Nelson-Riley function⁷ and extrapolating to $\theta = 90^\circ$. The results are shown in Table I. The unit cell

FIG. 1. Mössbauer spectra of $\text{Ni}_x\text{Co}_{1-x}\text{Fe}_2\text{O}_4$ at room temperature.

parameter (a_0) decreases linearly with increasing nickel concentration (x) and follows Vegard's law approximately. This can be expected in view of the fact that the ionic radius of 0.69 \AA for Ni^{2+} ions is smaller than that of 0.78 \AA for Co^{2+} ions. Mössbauer spectra of $\text{Ni}_x\text{Co}_{1-x}\text{Fe}_2\text{O}_4$ were measured at various absorber temperatures from 13 to 800 K. The Mössbauer spectra are composed of two six-line hyperfine pattern A and B sites. Using a least-squares computer program, two sets of six Lorentzians lines were fitted to the Mössbauer spectra under the usual constraints,⁸ which are valid when the quadrupole interaction is much weaker than the magnetic

FIG. 2. Reduced magnetic hyperfine field $H_{\text{hf}}(T)/H_{\text{hf}}(0)$ against reduced temperature T/T_N for the A and B sites of $\text{Ni}_{0.1}\text{Co}_{0.9}\text{Fe}_2\text{O}_4$. Points marked are the experimental values. The full curve is the Brillouin curve for $S = 5/2$.

FIG. 3. Temperature dependence of the ratio of A to B sites for $\text{Ni}_x\text{Co}_{1-x}\text{Fe}_2\text{O}_4$.

hyperfine interaction. Some of them are shown in Fig. 1. The results of the computer analysis are presented in Table I.

The isomer-shift values at room temperature for A and B patterns are found to be $(0.13-0.16) \pm 0.01$ and $(0.25-0.28) \pm 0.01 \text{ mm/s}$ relative to the Fe metal, respectively, which are consistent with the high-spin Fe^{3+} charge states.⁹ The smaller value of A-site isomer shift is due to a large covalency at the A site.

It is worth noting that in Fig. 1 and Table I the quadrupole shifts for both the A and B patterns vanish in accord with the cubic crystal structure of $\text{Ni}_x\text{Co}_{1-x}\text{Fe}_2\text{O}_4$. Plots of the reduced magnetic hyperfine field $H_{\text{hf}}(T)/H_{\text{hf}}(0)$ against reduced temperature T/T_N for the A and B sites of $\text{Ni}_{0.1}\text{Co}_{0.9}\text{Fe}_2\text{O}_4$ are given in Fig. 2 along with the Brillouin curve¹⁰ $B(S)$ for $S = 5/2$.

Figure 3 shows the temperature dependence of the absorption area ratio of A site to B site. It is worth noting in Fig. 3 that at low temperature the area ratio increases with increasing temperature and then decreases at high temperature. The cation distribution of $\text{Ni}_x\text{Co}_{1-x}\text{Fe}_2\text{O}_4$ is $(\text{Co}_y\text{Fe}_{1-y})^A[\text{Ni}_x\text{Co}_{1-x-y}\text{Fe}_{1+y}]^B\text{O}_4$, indicating the y of the tetrahedral site Fe^{3+} ions have migrated from A to B sites

FIG. 4. Natural logarithm of the absorption area, F , vs T^2 for the A and B subspectra of $\text{Ni}_{0.1}\text{Co}_{0.9}\text{Fe}_2\text{O}_4$.

FIG. 5. Debye temperatures for $\text{Ni}_x\text{Co}_{1-x}\text{Fe}_2\text{O}_4$.

(the same number of Co ions have moved from *B* to *A* sites). The area ratio of *A* and *B* subspectra for the above distribution¹¹ is

$$\frac{I_A}{I_B} = \frac{(1-y)f_A}{(1+y)f_B}, \quad (1)$$

where f_A and f_B represent the recoil-free fractions of *A* and *B* site Fe ions, respectively. The Debye model gives the following expression for the recoil-free fraction:¹²

$$f = \exp \left[- \frac{3E_R}{2k_B\theta} \left(1 + \frac{4T^2}{\theta^2} \int_0^{\theta/T} \frac{x dx}{e^x - 1} \right) \right], \quad (2)$$

where E_R is the recoil energy of ^{57}Fe for the 14.4 keV gamma ray. θ and k_B represent the Debye temperature and the Boltzmann constant, respectively. The Debye temperature for each site can be calculated from the temperature dependence of the resonant absorption area of each subspectra at low temperatures.

Figure 4 shows $\ln F$ vs T^2 for $\text{Ni}_{0.1}\text{Co}_{0.9}\text{Fe}_2\text{O}_4$, where F stands for the total resonance absorption areas of *A* and *B* sites a Mössbauer spectrum at T . F is proportional to the recoil-free fraction f . The curves are close to straight lines, and the results are $\theta_A = 679 \pm 5$ K and $\theta_B = 278 \pm 5$ K. Figure

FIG. 6. Temperature dependence of the fraction y of the tetrahedral site Fe^{3+} ions that migrate to *B* sites.

TABLE II. Atomic migration temperature, T_m and ratio of atomic migration, R_m at 700 K for $\text{Ni}_x\text{Co}_{1-x}\text{Fe}_2\text{O}_4$.

x	0.0	0.1	0.3	0.5	0.7
T_m (K)	400	420	450	470	520
R_m (%)	69	67	61	56	44

5 and Table II show the Debye temperature as a function of the nickel concentration x , for $\text{Ni}_x\text{Co}_{1-x}\text{Fe}_2\text{O}_4$. Since θ_B is much less than θ_A , it is evident from Eq. (1) that f_B decreases much more rapidly with increasing temperature than f_A ; f_A/f_B in turn increases with increasing temperature, thus explaining the tendency of the area ratio to increase with increasing temperature at low temperatures, as shown in Fig. 3. The tendency of the area ratio to decrease at high temperature in Fig. 3 can be explained in terms of the migration of Fe ions from the *A* sites to the *B* sites: in other words, an increase in the y value in Eq. (1) will result in a decrease in the area ratio.

Substituting the experimental area ratios from Fig. 3 and the f values from Eq. (2) into Eq. (1) we obtained the y values as a function of temperature, as shown in Fig. 6. It can be seen in Table II that the Debye temperature decreases with increasing nickel concentration x . Ni ions replacing Co ions seem to weaken the interatomic binding force between Co and O ions. Figure 6 shows that atomic migration of $\text{Ni}_{0.7}\text{Co}_{0.3}\text{Fe}_2\text{O}_4$ starts near 520 K and increases rapidly with increasing temperature to such a degree that 44% of the iron ions at the *A* sites move over to the *B* sites at 700 K. This onset temperature is higher by about 100 K than the for CoFe_2O_4 . An implication of this result is that increased Ni concentration enervates atomic migration.

Divalent zinc is commonly used as a replacement cation in ferrites, as it increases the material magnetization when substituted in moderate amounts. However, pure zinc ferrite (ZnFe_2O_4) is a normal spinel, as zinc has a strong preference for the tetrahedral (A) site in the spinel structure, with Fe occupying the octahedral (B) sites. Then antiferromagnetic B-B coupling dominates the magnetic behavior yielding a material with a Neel temperature near 10 K. It is typically difficult to produce inverted zinc ferrite due to this strong site preference, but recently we produced fine zinc ferrite powders having an inversion parameter of 0.20 using an aerogel process.¹ Ball milling these powders increased the inversion parameter to 0.55, and the median particle size from 14 to 40 nm. To confirm the x-ray diffraction inversion parameters, extended x-ray absorption fine structure (EXAFS) measurements were taken on these powders and ZnFe_2O_4 standards for both the Fe K_α and Zn K_α absorption edges. Fourier transformed results were fingerprinted against theoretical radial distribution functions generated from multiple-scattering FEFF codes for scattering atoms located on the tetrahedral and octahedral sites. Qualitatively, the zinc ferrite standard appears as a normal spinel, while both the iron and zinc radial distributions for the ball milled sample showed large site occupation of both A and B sites. This sample shows superparamagnetic behavior at room temperature, with some ferrimagnetic particles exceeding the critical volume, as indicated by a 15 Oe coercive field. The saturation magnetization of the metastable ball milled powder exceeds 2100 G. © 1996 American Institute of Physics. [S0021-8979(96)64508-5]

Densely sintered Mn–Zn ferrites with grain size varying between 1 and 6 μm were obtained. Then the effect of grain size was investigated in detail by power loss analysis and scanning electron microscopy examination of microstructure. It is found that the power loss is seen to be lowered from 260 to 120 kW/m^3 at 500 kHz, 50 m T and 90 °C with grain size decreased in the order of 3 μm . It is assumed that the residual loss from domain wall resonance is a dominant factor of power loss from 500 kHz to 1 MHz. Therefore we conclude that Mn–Zn ferrite display a grain size dependent power loss with transition at grain size about 3 μm due to the absence of intragranular domain wall and these fine core materials can be prepared by low sintering temperature and the optimum control of atmosphere containing 0.5% O_2 . © 1996 American Institute of Physics. [S0021-8979(96)30008-5]

I. INTRODUCTION

Because the driving frequency of switching power supplies has been raised from several kHz to around 1 MHz, there is an urgent need for the reduction of power loss of core material at high frequency. Mn–Zn ferrites, usually used as core materials in the switching power supplies, exhibit a high power loss at high frequencies. Therefore, many efforts have been made to reduce the power loss of Mn–Zn ferrites. Theoretically, power loss P_b is divided into three parts, hysteresis loss P_h , eddy current loss P_e , and residual loss P_r .¹ As P_e and P_r could not be measured experimentally, they are obtained by subtracting hysteresis loss. Besides, the magnetic domain configurations of polycrystalline Mn–Zn ferrites are not clear today. The wall-related loss P_r was generally ignored below MHz. Recently, several studies mentioned that P_r becomes dominant at this frequency range and at high temperature.² Moreover, the relation between grain size and domain size in Mn–Zn ferrite was also studied by neutron depolarization.³ It is found that the domain size is identical to the grain size for Mn–Zn ferrites for grain size between 0.3 and 3 μm . In this article, the present authors examined the effect of various grain sizes in low-loss Mn–Zn ferrites in order to resolve the above-mentioned problem. Power loss has been analyzed as a function of grain size in order to study wall-related power loss.

II. EXPERIMENT

Mn–Zn ferrite samples with the chemical composition $\text{Mn}_{0.72}\text{Zn}_{0.22}\text{Fe}_{2.06}\text{O}_4$, plus optimum CaO– SiO_2 content of 0.07 wt%, were prepared by conventional powder ceramic process. The samples with various grain size from 1 to 6 μm were sintered at 1170 °C in N_2 – O_2 atmosphere of 0.5% O_2 and obtained by adjusting the sintering time between 1 and 8 h.

Final dimensions of toroidal samples were 17 mm outside diameter (o.d.), 8 mm inside diameter (i.d.), and 5 mm

height. For electrical measurements, the specimen was 9 mm in diameter and 4 mm long, and both ends were indium gallium coated as an electrode.

Permeability was measured on toroidal samples by a LCR meter HP4284A. The power loss, P_b , was measured by an apparatus made by Ryowa Company. The hysteresis losses, P_h , were obtained by DC–BH tracer made by Walker company. Then, scanning electron microscopy (SEM) was used to observe the grain size.

III. RESULTS AND DISCUSSION

Table I shows that when samples were sintered at 1170 °C, densely sintered Mn–Zn ferrites with grain size varying between 1 and 6 μm were obtained. It is shown that with grain size around 3 μm , the optimum initial permeability is obtained, however the initial permeability decreases with further increase of grain size. This would be attributed to the effect of grain boundaries, because each grain of Mn–Zn ferrite is covered by a high-electrical-resistivity layer made of SiO_2 and CaO in order to prevent eddy current circulation. The thickness of high-electrical-resistivity boundary layer is believed to be influenced by the reduction of grain boundary thickness accompanying the increase of grain size. This phenomena causes the increase of dc resistivity and hysteresis loss for the samples with larger grain size. However, this layer also increases the apparent permit-

FIG. 1. Frequency dependence of resistivity for samples with various grain sizes.

tivity, so that at high frequency, these layers are short circuited by their capacitive properties. Figure 1 shows the frequency dependence of resistivity for samples with various grain sizes. It is found that although different dc resistivity is observed, the values of resistivity have similar frequency dependence above 500 kHz. According to a report,⁴ if the frequency dependence of resistivity is taken into account, a model can only approach the measured results in MHz region but can be quite different in the lower frequency range (500 kHz $< f < 1$ MHz). The magnetic domain configuration of polycrystalline Mn-Zn ferrites was not clear until now. P_b/f is expressed by the following equation:¹

$$P_b/f = kB^3 + \alpha \pi^2 S B^2 f / C \cdot \rho + P_r / f,$$

where k is a constant, B is the magnetic flux density, α is anomaly factor, S is the cross-section area, ρ is the microscopic electric resistivity, and C is the sample constant. P_b per cycle is plotted against frequency and shown in Fig. 2. Linear relationships were obtained for the sample with grain size $D = 3 \mu\text{m}$, but deviation from the linear behavior was found for samples with larger grain size ($6 \mu\text{m}$). The deviation

FIG. 2. Relationship between power loss per cycle and frequency at different induction levels.

FIG. 3. Dependence of $(P_b - P_h)/f$ on maximum flux density for samples with grain size 3 and $6 \mu\text{m}$.

from the linear behavior corresponds to residual loss¹ according the equation described above. The residual loss is close related to the number of domain wall. The reason is that resonance of ferrites arises from domain wall, dimensional, or natural resonance. We assume the observed residual loss was caused by domain wall movement, because the resonance frequency is considerably lower than the calculated natural resonance frequency and because P_r is independent of the sample dimensions. Besides, in Fig. 2 it is found that the residual loss tends to increase with frequency at higher magnetic flux density (50 m T) for the sample with grain size $D = 6 \mu\text{m}$. In other words, P_r cannot be ignored at this induction level.

On the other hand, we try to explain the domain configuration effect in terms of the empirical relation $W_e \propto B_m^y$.⁵ W_e and B_m represent $[(P_b - P_h)/f]$ and maximum flux density, respectively. Compared with the value of $y = 2$ for the Mn-Zn ferrite with grain size $D = 3 \mu\text{m}$, we find that $y > 2$ is observed for the sample measured at 500 kHz with grain size $D = 6 \mu\text{m}$ in Fig. 3. This finding correspond to the

FIG. 4. Temperature dependence of hysteresis loss per cycle for samples measured at d.c., 50 m T with various grain sizes.

FIG. 5. Relationship between $(P_b - P_h)/f$ and frequency for samples measured at 50 mT, 90 °C with various grain sizes.

model mentioned by Sato and Sakaki,⁵ which indicates that when $y > 2$ domain walls within the crystal are annihilated and generated repeatedly but there is no evidence of domain wall annihilation when $y = 2$.

As discussed above, we assume that with grain size on the order 3 μm , residual loss from domain wall resonance will be improved due to the absence of intragranular domain wall. The results also correspond to the findings that a transition in the intragranular domain structure from mono to two domains is observed by neutron depolarization at grain size $D = 3 \mu\text{m}$.³

In order to investigate the high-power performance of Mn-Zn ferrites, samples measured at high induction level 50 mT were studied further. Figure 4 shows the dependences of the hysteresis losses per cycle, W_h ($W_h = P_h/f$, J/m^3) on the temperature for samples with various grain sizes. It is shown that the variation of hysteresis loss with temperature is alike for the samples with grain size above 3 μm . Meanwhile, it is also noticeable that the values of hysteresis loss are identical for samples of 3 and 5 μm at 90 °C, however the difference of $(P_b - P_h)/f$ with frequency are remarkable for the two samples as shown in Fig. 5. It is proved that the hysteresis

FIG. 6. Temperature dependence of power loss for samples measured at 500 kHz, 50 mT with various grain sizes.

FIG. 7. SEM micrographs for samples with grain size (a) 3 μm and (b) 6 μm .

loss comprises a small part of P_b . Therefore, the power loss in the frequency range is mainly dominated by eddy current loss or residual loss. However, if the frequency variation of resistivity given in Fig. 1 is taken into consideration, it is believed the power loss is dominated by residual loss within the frequency range of 500 kHz–1 MHz. Although the residual loss will increase with increase of temperature, the sample with grain size $D = 3 \mu\text{m}$ still exhibits optimum power loss at 90 °C, as shown in Fig. 5. It is seen in Fig. 6 that the power loss is lowered dramatically from 260 to 120 kW/m^3 at 500 kHz 50 mT and 90 °C with grain size decreased in the order of 3 μm . Therefore, we conclude that a high-power-use Mn-Zn ferrites added with optimum CaO-SiO₂ content are improved by controlling the grain size around 3 μm and this fine material can be obtained by low temperature sintering. The SEM examination of microstructure is shown in Fig. 7 for two representative samples of this study.

Several fine powder samples of $\text{Zn}_x\text{Mg}_{1-x}\text{Fe}_2\text{O}_4$, $0 \leq x \leq 1$, were prepared by the supercritical sol-gel (aerogel) process, and were annealed at 500 °C for 2 h. The structure, crystallite size and inversion parameter were determined by x-ray diffraction. The crystallite diameter of the as-prepared powders ranged from 6.5 to 8.5 nm. The minimum size was achieved for the samples with $0.25 \leq x \leq 0.50$. After annealing the crystallite size increased by an average of 3 nm. The values of the inversion parameters, before and after annealing, reflect roughly the chemical preference of Zn cations to the tetrahedral sites and Mg cations to the octahedral sites of the spinel structure. However, these values indicate that the as-prepared materials were not in the equilibrium state. The magnetic properties were studied by ^{57}Fe Mössbauer spectroscopy over a temperature range of 25 K to room temperature. Taking advantage of their sensitivity to the superparamagnetic behavior induced by the size effects, the Mössbauer spectra were used to determine the blocking temperatures. The calculated values peaked at $x=0.50$ for both the as-prepared and annealed powders. SQUID magnetometry measurements are currently underway. © 1996 American Institute of Physics. Polycrystalline yttrium-iron-garnet (YIG) samples were sintered in air at temperatures ranging from 1350 to 1450 °C. Ferromagnetic resonance measurements have been accomplished at 11 GHz from 77 to 350 K. The different contributions to the linewidth have been analyzed. These results are compared with previous measurements of magnetic disaccommodation in the same samples. A qualitative relationship between both kind of measurements for polycrystalline YIG samples by means of an induced anisotropy formalism is provided. © 1996 American Institute of Physics. [S0021-8979(96)30108-1]

I. INTRODUCTION

Magnetic relaxation processes have been thoroughly studied in yttrium iron garnet (YIG), mainly in the initial stages of ferromagnetic resonance (FMR) research, due to the technological applications of this material because of its very low FMR linewidth.^{1,2} On the other hand in the past few years several works about new aspects in magnetic relaxation in YIG at low frequencies have appeared. These papers are mainly devoted to the aftereffect processes in single-crystal samples,³⁻⁵ which in some cases are illuminated or gamma-ray irradiated.^{6,7}

Our group has performed experiments both in low frequency (1 kHz) and FMR frequencies (11 GHz). At 1 kHz, magnetic disaccommodation (DA) has been measured for several series of polycrystalline YIG,^{8,9} FMR measurements are the purpose of the present article. Besides, in the last months our group has published results on nickel and lithium ferrites^{10,11} for which relations between DA and FMR measurements have been found. The comparison is attained by comparing the normalized value of the induced anisotropy constants calculated from DA and FMR experiments.^{10,11} In this article we present the relationships between DA and FMR found for YIG samples by means of an induced anisotropy formalism.

II. EXPERIMENT

A series of polycrystalline samples with nominal composition $Y_3Fe_5O_{12}$ has been prepared from stoichiometrically mixed high-purity powders of Fe_2O_3 and Y_2O_3 . The mixtures were ball milled in an agate mortar, pressed in a cylindrical die, and sintered for 8 h in air atmosphere at temperatures ranging from 1350 to 1450 °C according to the phase diagrams of the system Y-Fe-O.¹² Finally, vacancy annealing was avoided by rapid quenching in an air stream.

Disaccommodation was measured recording the variation of the initial permeability with time after the sample demagnetization.¹³ In this way isothermal curves are obtained but, as is usual in the literature, we have chosen a representation in terms of the isochronal relaxation curves which show the relative variation of permeability at different rate windows:

$$\frac{\Delta\mu(t_1, t_2, T)}{\mu(t_1, T)} = \frac{\mu(t_1, T) - \mu(t_2, T)}{\mu(t_1, T)}, \quad (1)$$

where in our experiences $t_1 = 2$ s and t_2 varies between 4 and 256 s. The experimental results are processed by using the analysis techniques described in Ref. 14.

FMR linewidth measurements were basically accomplished by monitoring the reflected wave in a short-circuited standard subminiature A (SMA) coaxial transmission line. The reduced size of this line facilitates the implementation of the system in a conventional cryostat. The temperature of the cryostat chamber is controlled by an intelligent temperature controller with a stability better than 0.1 K. An additional platinum resistance located outside the short-circuit at 2 mm from the sample registers its temperature.

The linewidth is obtained by sweeping the static magnetic field around the resonance situation for each temperature and storing in the computer the relative reflected power. As is well known, this microwave absorption is proportional to the imaginary part χ_e'' of the diagonal component χ_e of the external susceptibility tensor χ_e (Ref. 1) and the linewidth ΔH is defined as the midheight width of the curve χ_e'' vs H (static magnetic field). The linewidths ΔH presented here are calculated, according to this classical definition, fitting the experimental points by means of a nonlinear computational technique. The whole process is automatized so that the dependence with temperature of the FMR linewidth can be obtained in a few hours.¹⁰

III. RESULTS AND DISCUSSION

DA measurements were performed previously and the results can be found in detail in Ref. 9. As can be seen in Fig. 1 for the YIG sample sintered at 1350 °C, a relaxation peak process appears in the isochronal spectrum around 130 K. A similar peak appears for all the samples but its amplitude depends on the sintering temperature. Besides, for the samples sintered at 1420 and 1450 °C there is a shift in the maximum to higher temperatures.⁹

FMR linewidths measured at 11 GHz from 77 to 350 K can be observed in Fig. 2. The lowest linewidths are obtained

FIG. 1. Disaccommodation isochronal spectrum for YIG sintered at 1350 °C ($t_1=2$ s and $t_2=4, 8, 16, 32, 64$, and 128 s).

for the YIG samples sintered at 1415 °C, for this sample the DA isochronal spectrum also showed the peak with least amplitude (see Fig. 4).

In order to achieve a comparison between DA and FMR we have to look for the effect of induced anisotropy in FMR measurements. According to Krupicka *et al.*¹⁵ this effect underlies the peak processes whose maximum with temperature is frequency dependent. The relaxation mechanisms involved in these peak processes are valence-exchange and slowly relaxing impurities.¹ So the first step to take is to separate the different contributions to the linewidth. We have considered the typical contributions to the polycrystalline linewidth ΔH ,¹⁰

$$\Delta H = \Delta H_p + \Delta H_a + \Delta H_s, \quad (2)$$

where ΔH_p is the contribution induced by the porosity, ΔH_a is the broadening due to the random orientation of the an-

FIG. 2. FMR linewidth from 77 to 350 K for the YIG samples sintered at different temperatures.

FIG. 3. Theoretical fitting together with the experimental linewidths for the YIG sample sintered at 1420 °C.

isotropy axes of the different crystallites of the polycrystal, and ΔH_s is the linewidth of the single crystal.

ΔH_s should include the following contributions: intrinsic contribution of the Kasuya-Le Craw type,¹ surface roughness, valence exchange, slowly relaxing impurities, and rapidly relaxing impurities.¹ Here we will not consider the intrinsic and surface contributions because their magnitude is negligible when we are dealing with polycrystalline linewidths of some hundred of oersted. We will also not consider the rapidly relaxing impurities contribution because it should exhibit a linear dependence with frequency which has not been observed. After these considerations ΔH_s will include just valence exchange and slowly relaxing impurities. These temperature peak processes are the ones mechanisms related to the induced anisotropy.

According to DA measurements⁹ some Fe^{2+} ions are present in our samples so that valence exchange is possible there could also be some impurities acting as slow relaxers. We have then supposed a general temperature peak process contribution which would have the form,¹

$$\Delta H = C \frac{\omega \tau_r}{1 + (\omega \tau_r)^2}, \quad (3)$$

where C is a constant, with τ_r being

$$\tau_r = \tau_0 \exp \frac{Q}{kT}, \quad (4)$$

where τ_0 is the preexponential relaxation time and Q the activation energy. Taking $\tau_0=10^{-13}$ s and $Q=10^{-2}$ eV, typical for electronic processes,¹ we have fitted the linewidths of Fig. 2 obtaining the best value for the constant C of Eq. (3). The contributions of porosity and anisotropy have been computed using the expressions of Sparks¹ as in our previous work.¹⁰ The fitting obtained for the sample sintered at 1420 °C is shown in Fig. 3.

In order to compare DA and FMR measurements we have shown in Ref. 10 that a qualitative relation can be

FIG. 4. Dependence with the sintering temperature of the amplitude of the DA peak and the value of the constant C from the FMR peak process.

achieved through the induced anisotropy constants. These constants are proportional both to the amplitude of the DA peaks and to the value of C of expression (3). A quantitative comparison is not possible mainly because in DA measurements just the temporal variations of the permeability after demagnetization are computed, so that absolute values of permeability are not obtained. Anyway a qualitative study of the effect of induced anisotropy in DA and FMR can be accomplished comparing the DA peak amplitude and the C constant [Eq. (3)] for the different samples. In Fig. 4 results of the DA peak and C for the YIG samples sintered at different temperatures can be observed. It can be noted how the effect of the induced anisotropy is similar in the two kinds of measurements—it decreases with sintering temperature until 1415 °C. For sintering temperatures higher than 1415 °C an increase in the effect of induced anisotropy is found although this increase is larger in DA than in FMR. These deviations could be related to the presence of diffusants similar to those found by Guyot *et al.* in their works about polycrystalline YIG.^{16–19}

IV. CONCLUSIONS

As a summary we could conclude that DA and FMR measurements have been qualitatively compared for poly-

crystalline YIG sintered at different temperatures. This comparison has been carried out by means of an induced anisotropy formalism. The effect of the induced anisotropy is similar in both kinds of experiments but for samples sintered at temperatures higher than 1415 °C some deviations appear. These deviations are related to the presence of diffusants, previously found in other studies,^{16–19} which mainly affect DA processes.

$\text{BaFe}_{12-(x+y)}\text{Sn}_x\text{Co}_y\text{O}_{19}$ single crystals, with $0 \leq x \leq 2$ and $0 \leq y \leq 2$, have been grown from high temperature solution by slow cooling using the TSSG method. Magnetic properties of these single crystals have been investigated using a commercial quantum design SQUID magnetometer in the temperature range 6 to 320 K and with a varying field from -5 to $+5$ T applied parallel and perpendicular to their c axis. It is found that the replacement of part of the Fe^{3+} ions by Co^{2+} and Sn^{4+} ones reduces the anisotropy as well as the saturation magnetization of the materials. For a small amount of substitution, the magnetization as a function of applied fields, which were oriented in the c axis, exhibits a hysteresis loop indicating that the magnetic domain wall moving was pinned by the imperfections of magnetic structures. When the substitution was increased to $x + y = 2.5$, long distance magnetic coupling was destroyed, and the sample behaved as a magnetic granular material consisting of randomly distributed magnetic clusters. © 1996 American Institute of Physics. α'' -Fe₁₆N₂ single crystal films can be prepared successfully by facing targets sputtering directly onto NaCl(100) substrates in a mixture of argon and nitrogen gases. Both x-ray diffractometer and transmission electron microscope are employed to characterize the crystal structure of the films. The perfect electron diffraction patterns of α'' -Fe₁₆N₂ single crystal in $[\bar{1}11]$, $[011]$, and $[001]$ directions can be distinctly observed by double tilting. These patterns confirm that the crystal structure of the films corresponds to a body-centered tetragonal (bct) lattice with the parameters of $a=b=5.72$ Å and $c=6.29$ Å. The x-ray diffraction patterns show that α'' -Fe₁₆N₂ epitaxially grows on the NaCl(100) substrate with an orientation relationship α'' -Fe₁₆N₂(001) || NaCl(001) and α'' -Fe₁₆N₂[100] || NaCl[100]. The saturation magnetization of the Fe₁₆N₂ films is around 2100–2300 emu/cc, which agrees well with the value reported by Sugita *et al.* © 1996 American Institute of Physics. [S0021-8979(96)30208-8]

I. INTRODUCTION

The Fe-N binary system was thoroughly investigated by Jack^{1,2} in the early 1950s. In the iron nitride diagram, α'' -Fe₁₆N₂ phase with a deformed body-centered tetragonal (bct) structure is of great importance. It is reported by Kim and Takahashi³ that α'' -Fe₁₆N₂ has a giant saturation magnetic flux density ($B_s=2.58$ T) which was 17% larger than that of pure iron. The deduced B_s of α'' -Fe₁₆N₂ would be 2.83 T from the volume ratio of α'' -Fe₁₆N₂ in the film. Many researchers have been trying hard to synthesize pure α'' -Fe₁₆N₂ into both bulk^{4–6} and thin film^{7–19} forms by various methods. However, only a few have succeeded in fabricating single phase Fe₁₆N₂; most deposition techniques tend to obtain multiphase products.

Inspiring progress has been made by Sugita and his co-workers.^{13,14} They succeeded in growing single crystal α'' -Fe₁₆N₂ film on Fe(100)/In_{0.2}Ga_{0.8}As(100) substrates using molecular beam epitaxy (MBE). They reported that the B_s of α'' -Fe₁₆N₂ would be 2.8 T at room temperature. In their subsequent papers,¹⁴ the B_s of α'' -Fe₁₆N₂ is determined to be 3.2 T at liquid helium temperature, which corresponds to the average magnetic moment of $3.5 \mu_B$ per Fe atom, and therefore, is far beyond the Slater–Pauling curves. Very recently, Ortiz *et al.*¹⁸ claimed their success in epitaxially growing single crystal α'' -Fe₁₆N₂ films on single crystal MgO substrates by reactive sputtering. But the average magnetic moment is only 250 emu/g (1853 emu/cc) in the experiment.

The saturation magnetization of α'' -Fe₁₆N₂ estimated from different experiments was considerably diverse especially between bulk and film forms,^{6,14} ranging from 226 emu/g¹⁵ which is close to that of bcc iron to the very giant

value of 310 emu/g.¹⁴ Moreover, there have been several theoretical studies^{20–22} to expound the high saturation magnetization. However, no calculations based on band structure can successfully explain the giant magnetization and its origin is still mysterious in theory.

In this paper, we have been able to obtain single crystal α'' -Fe₁₆N₂ films on NaCl(100) substrates. We also distinctly observed a series of electron diffraction patterns with perfect symmetry in the directions of $[\bar{1}11]$, $[011]$, and $[001]$. The vibrating sample magnetometer (VSM) measurement shows that the α'' -Fe₁₆N₂ film has saturation magnetization as large as ~ 2200 emu/cc, which gives strong support to that reported by Sugita *et al.*^{13,14}

II. EXPERIMENTAL PROCEDURES

The Fe-N films were prepared by facing targets sputtering (FTS) onto NaCl(100) single crystals with freshly cloven surface. The lattice constant of NaCl is 5.63 Å, which is smaller by only 1.6% than that of a -axis of Fe₁₆N₂ (5.72 Å). This provides the possibility of epitaxial growth. The base pressure was 6×10^{-5} Pa. The working gas is a mixture of argon and nitrogen. During sputtering, the partial pressures of Ar and N₂ gases were held constant at 0.3 Pa and 0.05 Pa, respectively. The deposition rate was 2.0 Å/s, and the substrate temperature was about 150 °C.

The crystal structure was examined with a Rigaku x-ray diffractometer (XRD) with Cu $K\alpha$ radiation and a JEM-200CX transmission electron microscope (TEM) operating at 200 keV. The saturation magnetization was measured at room temperature by VSM with a resolution of 2×10^{-6} emu in an external magnetic field of 8 kOe which was applied parallel to the sample plane. The hysteresis loop of the

FIG. 1. The XRD patterns of Fe_{16}N_2 (400 Å) on $\text{NaCl}(001)$ substrate.

NaCl substrate and the holder was measured and the magnetic moment was about 1–2 orders of magnitude lower than that of the samples. The hysteresis loops of the samples were then measured and the magnetization of the holder and substrates was subtracted automatically by a computer during measuring. The thickness of the films was monitored by an *in situ* quartz oscillator in the system. The total error involved in the measurement of the magnetization was safely estimated to be no more than 6%.

III. RESULTS AND DISCUSSION

Figure 1 shows the XRD patterns of the Fe_{16}N_2 film deposited directly onto $\text{NaCl}(100)$ substrate. There is an intense $\alpha''\text{-Fe}_{16}\text{N}_2(004)$ peak and a weak $\alpha''\text{-Fe}_{16}\text{N}_2(002)$ peak in the pattern. This reveals that Fe_{16}N_2 has the same crystallographic orientation as the NaCl substrate. From the point of view of x-ray diffractometry, it is regarded that $\alpha''\text{-Fe}_{16}\text{N}_2$ grows epitaxially on the NaCl substrates with the following orientation relationships:

$$\alpha''\text{-Fe}_{16}\text{N}_2(001) \parallel \text{NaCl}(001),$$

$$\alpha''\text{-Fe}_{16}\text{N}_2[001] \parallel \text{NaCl}[001],$$

i.e., the growth plane is (001) with c -axis perpendicular to the film plane, which is quite different from the case of (110) growth on InGaAs substrate.¹⁴ The interplanar spacing of $\alpha''\text{-Fe}_{16}\text{N}_2(200)$ is 2.86 Å, while that of $\text{NaCl}(200)$ is 2.815 Å. The unit cell of $\alpha''\text{-Fe}_{16}\text{N}_2$ grows on one single unit cell of NaCl , and the mismatch between Fe_{16}N_2 and NaCl is only 1.6%. This guarantees the epitaxial growth with the above-mentioned orientation relationships. By the Scherrer formula, the calculated mean crystalline size of single crystal $\alpha''\text{-Fe}_{16}\text{N}_2$ is about 500 Å from the full width at half maximum of the peak in the XRD pattern.

TEM was employed to further characterize the crystal structure of Fe_{16}N_2 . Figure 2 shows the selected area electron diffraction (SAED) patterns. A series of SAED patterns are obtained by means of double tilting. Figure 2(a) is the SAED pattern with $[\bar{1}11]$ incidence of $\alpha''\text{-Fe}_{16}\text{N}_2$ single crystal. The spots displaying a quasi-sixfold symmetry (caused by the difference between a and c parameters) are denoted as tetragonal body-centered lattice. Figure 2(b) is the illustration of SAED pattern with $[\bar{1}11]$ incidence of $\alpha''\text{-Fe}_{16}\text{N}_2$ single-crystal corresponding to Fig. 2(a). The representative indexing results are listed in Table I. Figure 2(c)

FIG. 2. The selected area electron diffraction (SAED) patterns of Fe_{16}N_2 (400 Å) film: (a) with the incidence of $[\bar{1}11]$; (b) the schematic illustrations of SAED patterns corresponding to (a); (c) with the incidence of $[011]$ by means of double tilting; (d) with the incidence of $[001]$.

shows the SAED pattern in $[011]$ direction at an angle of 37.8° to $[\bar{1}11]$ direction while Fig. 2(d) is the pattern at an angle of 52° to $[\bar{1}11]$ which is the incidence direction of $[001]$. The representative indexing results are also listed in Table I. One can see that all three patterns display a perfect symmetry. By the way, in Figs. 2(c) and 2(d) the presence of rings may be due to the damage on the crystal structure by electron irradiation. It may take some time to seek the zone-axis by double tilting.

Previously, the Hitachi group gave the SAED pattern of Fe_{16}N_2 single crystal in $[001]$ direction by a cross sectional TEM.¹⁴ However, the spatial distribution of the diffraction spots didn't exhibit perfect symmetry. This paper gives the perfect electron diffraction patterns of $\alpha''\text{-Fe}_{16}\text{N}_2$ single crystal in the three directions of $[\bar{1}11]$, $[011]$, and $[001]$ simultaneously for the first time. Moreover, the pattern in $[\bar{1}11]$ direction instead of $[001]$ represents the characteristic

M_s (emu/cc)	2289	2270	2210	2125	2182

of bct Fe_{16}N_2 , for the large interplanar distances of (011) (4.23 Å), and (110) (4.045 Å) are unlikely to be confused with those of other Fe-N phases. It is of interest to note that the behaviors of the three SAED patterns are different, i.e., showing different zero rules. In the [011] and [001] directions, the spot intensity obeys the zero rule of fcc lattice, i.e., (hkl) spots disappear if h, k, l are odd-even mixed. On the contrary, in $[\bar{1}11]$ direction, the spot intensity shows the bcc lattice zero rule, i.e., the spots vanish if $(h+k+l)$ is an odd integer. It is well known that the observed diffraction pattern is equivalent to the points of intersection of the Ewald sphere of radius $1/\lambda$ with the reciprocal-lattice nodes. When Bragg condition is satisfied, by neglecting the lattice amplitude which depends only on the external shape of the crystal, the structure amplitude which depends only on the position of the atoms inside the unit cell is decisive to the spot intensity. And consequently, it is rather difficult to understand our present experimental results.

It is worth mentioning that the substrate temperature is crucial in preparing single crystal Fe_{16}N_2 film. Substrate temperature may influence the diffusion process of the atoms on the substrate. When the substrate temperature is higher than 180 °C, the nitrogen atoms become more active and then it is more likely to form γ' - Fe_4N with a high nitrogen concentration. When the substrate temperature is lower than 100 °C, it tends to form α' -martensite instead of α'' - Fe_{16}N_2 .¹⁹

In order to clarify the saturation magnetization of Fe_{16}N_2 single crystal films, the VSM measurement is employed and the results are listed in Table II. The values are distributed around ~ 2200 emu/cc. Considering the errors involved in the VSM measurement and the volume estimation, the M_s of Fe_{16}N_2 single crystal is reasonably expected to be 2200 emu/cc, which is in good agreement with the results of Kim *et al.*³ and of Sugita *et al.*¹⁴ It is quite different from the theoretical calculated values by Sakuma,²⁰ Min,²¹ and Coehoorn *et al.*²² Thus the origin of the giant saturation magnetization is still confusing. It is regarded^{11,14} that the volume expansion and charge transfer effects are responsible for the high saturation magnetization of Fe_{16}N_2 . Recent theoretical work by Papanikolaou *et al.*²³ indicates that nitrogen, as either a substitutional or interstitial impurity in alkali metals, may have quite a sizable magnetic moment of between 1.5–3.0 μ_B . However, the band calculated moment value of nitrogen is only 0.05 μ_B by Min²¹ and $-0.03 \mu_B$ by Coehoorn *et al.*²² This reminds the authors that it is desirable to treat the moment of nitrogen atoms in a more satisfactory manner

in theoretical calculation rather than accept the previous results.

IV. CONCLUSION

In summary, α'' - Fe_{16}N_2 single crystal films can be successfully prepared by the FTS method directly onto single crystal NaCl(001) substrates, at a deposition rate as high as 2.0 Å/s. The epitaxial growth relationships can be figured out as α'' - Fe_{16}N_2 (001) \parallel NaCl(001), α'' - Fe_{16}N_2 [001] \parallel NaCl[001]. The perfect electron diffraction patterns of α'' - Fe_{16}N_2 single crystal in the directions of $[\bar{1}11]$, [011], and [001] were distinctly observed. The saturation magnetization of α'' - Fe_{16}N_2 is measured to be around 2200 emu/cc, which agrees well with that reported by Sugita *et al.*¹⁴ within experimental errors. The origin of such an ultra-high M_s is still unclear.

(100)-textured 3% silicon steel sheets by manganese removal and decarburization

Toshiro Tomida

Corporate Research and Development Laboratories, Sumitomo Metal Industries, Ltd., 1-8 Fuso-cho, Amagasaki 660, Japan

Texture development in 3% Si steel sheets by the manganese removal and decarburization process has been investigated. The 3% Si steel sheets that contain Mn and C were first annealed in vacuum at α -ferrite (α)/austenite (γ) duplex or γ phase temperatures, and then decarburized. During the vacuum annealing a manganese removal induced phase transformation to α occurs in a thin layer near the sheet surface. Pronounced (100) textures with a variety of in-plane anisotropies develop in the layer. The subsequent decarburization promotes the growth of the surface grains into the interior, providing the entire sheet with the same texture. The resultant materials exhibit excellent soft-magnetic properties. © 1996 American Institute of Physics. [S0021-8979(96)30308-4]

I. INTRODUCTION

Although the (100) texture development in silicon steel sheets was the subject of extensive studies in the late 1950s and 1960s,¹⁻⁴ the subsequent 30 years have seen little progress. The texture for which (100) is parallel to the sheet surface maximizes the number of easy magnetization directions of the steel in the sheet plane and is therefore ideal for the magnetic core of rotating machines and transformers in which magnetic flux travels along multiple directions in the plane. Nevertheless, no current commercial steel closely approaches this texture.

Recently an enticing process for the (100) texture development by manganese removal and decarburization (MRD process)⁵ has been discovered. This process is a two-stage annealing of Si steel sheets that contain Mn and C. During the first annealing a manganese removal occurs, and decarburization takes place in the second. A pronounced (100) texture has been reported to form in 2% Si steel sheets of 0.5 mm in thickness. However, the applicability of the MRD process to steel with higher silicon concentrations is unclear, although the increase in Si concentration will lower core loss because of the reduction in eddy current loss. The purpose of this research is, therefore, to examine whether the (100) texture develops in 3% Si steels by the MRD process and to investigate the effects of the texture development on magnetic properties.

II. EXPERIMENTAL PROCEDURE

Vacuum melted steels of the composition listed in Table I were made at the research laboratory. The resulting ingots from A to D were hot rolled to 5.0-mm-thick plates, ma-

chined to remove oxidized surface layers to 3.0- (A and B) and 1.5-mm- (C and D) thick plates, and then cold rolled to the final gauge of 0.35 mm in thickness. The ingot E was hot rolled to 4.0-mm-thick plates, pickled, and cold rolled to the same final gauge. They were then subjected to the MRD process as follows. The specimens were first annealed in a vacuum of 10^{-3} Pa at α -ferrite (α)/austenite (γ) duplex or γ phase temperatures of around 1000 °C for periods up to 12 h (the annealing for removal of manganese).⁵ They were then decarburized at 1000 °C in a dry hydrogen gas or at 850 °C in a wet 20% hydrogen-argon gas mixture of 10 °C of the dew point.

The chemical composition, microstructure, texture, and magnetic properties of the specimens were investigated. The texture was measured by using pole figure and inverse pole figure techniques. These methods were used to measure the pole densities, $(I/I_R)_{hkl}$, where $(I/I_R)_{hkl}$ refers to the ratio of the x-ray integrated intensity of a particular plane for a given sample to the integrated intensity of the same plane for a "random" powder sample. Magnetic properties were measured by a single strip tester with 30×100 mm strips or by using ring-shaped specimens of which the inside and outside diameters are 33 and 45 mm, respectively. The strips and rings for the measurement were cut from the specimens and stress relieved by annealing at 800 °C for 1 h in an argon atmosphere. To investigate the effects of sheet thickness and stress on magnetic properties, some strip samples were thinned by chemical etching and magnetic properties were measured applying tensile stresses of up to 8×10^6 Pa in the magnetizing direction.

FIG. 3. Effect of vacuum-annealing temperature on the texture of the surface α layer. The annealing time is 9 h.

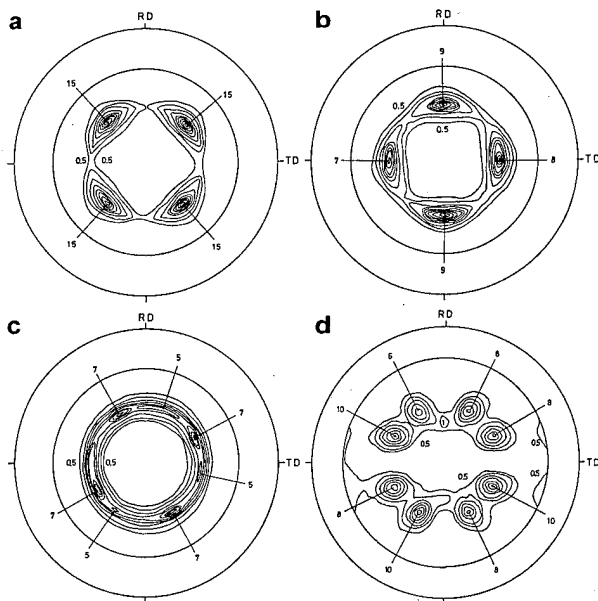

FIG. 4. The (110) pole figures showing variation of the in-plane anisotropy of the (100) texture. The textures of steels A (a), C (b), D (c), and E (d) are approximately as (100) [011], (100) [001], (100) [0vw], and (100) [021], respectively. The steels A–D and E were vacuum annealed at 950 °C for 9 and 12 h, respectively.

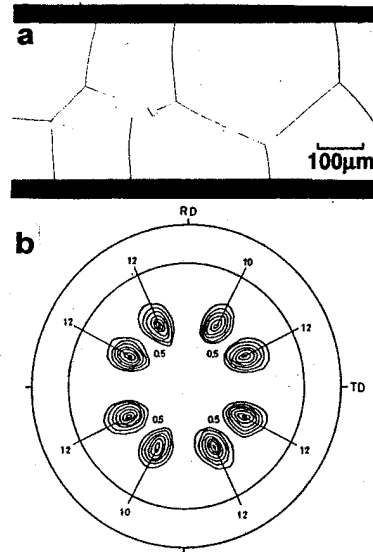

FIG. 5. Optical photograph of the cross section (a) and (110) pole figure (b) for steel E vacuum annealed at 950 °C for 12 h and decarburized at 1000 °C for 1 h in a dry hydrogen.

III. RESULTS AND DISCUSSION

The microstructure typical of the vacuum-annealed specimen is shown in Fig. 1. The annealing temperature in this case, 950 °C, is α/γ duplex and γ phase temperatures for steels A and B, respectively. The microstructures of the inner portions of the specimens, the fine equiaxial grain structure (for steel A), and coarse grains (for steel B) with carbide precipitates (dark particles), correspond to the above phase states at the annealing temperature. On the other hand, just below the sheet surface exist thin layers of about 50 μm in thickness without carbide precipitates. These surface layers without carbides indicate that an isothermal phase transformation to α occurs near the surface during this stage of annealing. We will refer to this layer without carbides as the “surface α layer.”

As shown in Fig. 2, the thickness of the surface α layer increases (with increasing annealing time, t) linearly with the square root of t . Correspondingly, the concentration of Mn also decreases linearly with \sqrt{t} , whereas the C concentration scarcely changes. Note that this compositional analysis is not for the surface α layer but for the entire sheet. The “averaged” Mn concentration decreases by 30%, when annealing steel A at 1000 °C for 9 h. Therefore, the removal of Mn occurs at this stage of annealing, and causes the formation of the surface α layer. It is believed that the significant Mn depletion near the surface increases the chemical potential of

0.2	7.6	1.805	0.55	0.78	0.37

carbon and that, as a consequence, the carbon atoms near the surface diffuse into the interior, resulting in a significant reduction in C concentration near the surface. This causes the transformation to the single α phase.⁵ The Mn removal is thought to be due to the evaporation of Mn, of which the equilibrium vapor pressure is as high as 0.4 Pa at 950 °C.⁶ Moreover the \sqrt{t} dependence of the surface α layer thickness and Mn concentration suggests that the growth of the surface α layer is mainly controlled by the diffusion of Mn.

The (100) texture has been observed to markedly develop within the surface α layer during the vacuum annealing. As shown in Fig. 3, the (200) pole density has increased over 50, in expense of other pole densities, by vacuum annealing at the temperatures ranging from 950 to 1050 °C for 9 h for all steels under investigation. This insensitivity of the (100) texture development to the chemical compositions and preannealing processing conditions supports the hypothesis that the selective driving force for the texture development is the anisotropy of surface energy.⁵

The in-plane anisotropy of the (100) texture, however, varies depending upon the chemical compositions and the preannealing processing conditions. Figure 4 shows such a variation of the in-plane anisotropy. The textures with some spread around (100) [001], (100) [011], and (100) [021] and an approximately random cube texture have been observed. An investigation is underway on the mechanism that determines the in-plane anisotropy.

The subsequent decarburizing annealing at α/γ duplex or γ phase temperatures results in a structure consisting of grains of several hundred μm in diameter without carbide precipitates, as seen in Fig. 5(a). Interestingly enough, the texture of the decarburized sheet is almost the same as that of the surface α layer formed by the preceding vacuum annealing [compare Figs. 5(b) and 4(d)]. This clearly suggests that, under proper decarburizing conditions, the grains in the surface α layer preferentially grow inward and this grain growth dominates the structure change at this stage of annealing.

As expected by the highly developed (100) texture and relatively fine grain structure, the MRD-processed sheets exhibit excellent magnetic properties. The typical magnetic properties measured with ring specimens are listed in Table II. For example, the relative permeability at 1.5 T is 4500,

and the core loss at 1.5 T and 50 Hz, $W_{15/50}$ is 1.4 W/kg. That is, the MRD-processed 3% Si steel sheets have approximately twice the permeability at 1.5 T as conventional 3% Si nonoriented electrical steel sheets,⁷ and the core loss is about two-thirds. Moreover a small in-plane magnetic anisotropy, which is desired for the magnetic core of rotating machines, can be attained not only by the approximately random cube texture but also the (100) [021] texture shown in Fig. 5. Since the (100) [021] texture consists of two inclined cube components that are rotated by about $\pm 26^\circ$ from (100) [001] around [100], the magnetic anisotropies of the two components nearly cancel each other. The change in the magnetic flux density at 5000 A/m, B_{50} , in the sheet plane is 0.1 T for the specimen shown in Fig. 5 and Table II, which is only 5.7% of the averaged B_{50} .

An increased in-plane anisotropy leads to a higher magnetic flux density and a lower core loss in two directions perpendicular to each other. In Table III are listed the magnetic properties of the specimen with the (100) [011] texture; the magnetizing direction is inclined by 45° from the rolling direction in the sheet plane, i.e., easy magnetizing direction. The magnetic flux density at 1000 A/m, B_{10} is about 1.81 T. The core loss at 1.7 T and 50 Hz, $W_{17/50}$ is 1.40 and 1.03 W/kg for the 0.3- and 0.2-mm-thick sheets, respectively, and it decreases markedly when a tensile stress is applied. This decrease in core loss by the stress is primarily due to the decrease in hysteresis loss (see Table III). It is also worth noting that, although the B_{10} of the specimen is not as large as that of today's grain-oriented 3% Si steel sheets (GO),⁷ the core loss is comparable to that of GO. The mechanism of this reduced core loss, which must relate to the fine grain structure, and modifications of the process to maximize the magnetic anisotropy obviously deserve further investigation.

Deposition condition and thickness dependence on magnetic properties of sputtered NiFeCo thin films

A. Tsoukatos and S. Gupta

Materials Research Corporation, Orangeburg, New York 10962

Y. K. Kim

Quantum Peripherals Colorado Inc., Louisville, Colorado 80028

The soft magnetic properties of polycrystalline NiFeCo films have been investigated in the thickness range of 20–2400 Å. The films were deposited by dc magnetron sputtering, at 5 Å/s, from a $\text{Ni}_{66}\text{Fe}_{16}\text{Co}_{18}$ high purity target, and under an applied magnetic field of 85 Oe. The effects of deposition pressure on the film crystal structure and magnetic properties have been investigated via x-ray diffraction and magnetic measurements. Both easy and hard axis coercivity values decrease significantly as the deposition pressure was changed from 7 to 3 mTorr, with the corresponding effects observed in the magnetoresistance and anisotropy field values, respectively. The magnetic data at 3 mTorr showed a nonlinear behavior at thicknesses below 1000 Å, while at 7 mTorr the nonlinearity is present in both the low and high end thicknesses. © 1996 American Institute of Physics. [S0021-8979(96)30408-0]

I. INTRODUCTION

Complex thin film structures of NiFe/Ag^{1,2} and NiFeCo/Ag, Cu^{3–6} have been used for the development of magnetoresistive elements of considerable sensitivity at room temperature. However, unlike the Fe⁷ and the NiFe^{8,9} soft magnetic films, the properties of the soft magnetic component in these structures, the ternary NiFeCo alloy, have not been investigated under similar deposition conditions. It is the objective of this work to investigate the crystal structure and the magnetic properties of this NiFeCo alloy over a wide range of thicknesses.

The deposition conditions were chosen in order to ensure single layer integrity and repeatability in the thinner layer regime, although at lower deposition rates the grain growth caused the coercivity values to increase. However, the importance of high quality multilayer structures, for subsequent thermal processing for giant magnetoresistance (GMR) optimization, dictates the range of deposition rates³ and the relevant magnetic properties and crystal structures of the single layer were therefore addressed at identical deposition conditions.

II. EXPERIMENTAL PROCEDURES

Single layer NiFeCo samples were deposited over the thickness range of 20–2400 Å. The films were grown on 3 in. thermally oxidized silicon (100) substrates, with base deposition pressures of the order of 10^{-8} Torr. The films were dc magnetron sputtered at dynamic argon pressures of 3 and 7 mTorr, with corresponding deposition rates of 5 Å/s. A magnetic field of 85 Oe was applied to the substrate during the film growth, so that magnetically oriented films were obtained.

Film thickness was determined using a Tencor P1 profilometer. For the thinner NiFeCo films, thickness uniformity data were obtained from four point probe measurements, which in correlation with the low angle diffraction data were used to evaluate these films. The crystal structure of the films was determined via x-ray diffraction (XRD), from high and

low angle spectra. Low angle diffraction was used to quantify the repeatability of the thin NiFeCo layers and it was obtained from stacks of ten (Ag/NiFeCo) bilayers. The latter work was also done in correlation to Ref. 3, where good quality layered structures are important for the subsequent GMR performance of these films. The upper NiFeCo layer was protected from oxidation by the deposition of a 100 Å silver layer.

Magnetic measurements were done on a SHB-109 BH loop tracer at applied fields of 50 Oe. Four point probe measurements were used for the determination of the magnetoresistance (MR) change in the films as a function of film thickness. A vibrating sample magnetometer (VSM) was also used to identify the saturation magnetization values of these single layer films.

III. RESULTS AND DISCUSSION

A. Crystal structure

XRD studies were used for the crystal structure identification of the single layer NiFeCo films. Figure 1 shows the XRD spectra of two 2400 Å films as deposited at 3 and 7 mTorr. The characteristic (111), (200), and (211) fcc lines are present for both film structures. The overall crystal structure present in these films is polycrystalline face centered cubic. The effect of higher deposition pressure results in a less pronounced spectrum intensity, possibly due to excess scattering of the incident beam, at surface inhomogeneities induced by the film porosity.

Verification of the integrity and repeatability of the thinner films studied (i.e., 20, 50 Å in thickness) required the use of low angle XRD along with the regular high angle scans. These samples were evaluated in stacks of ten bilayer structures, which consisted of NiFeCo and Ag layers. The Ag layer thickness was kept constant at 100 Å, while the NiFeCo layer thickness was varied from 20 to 100 Å. The insert of Fig. 2 shows the low angle XRD spectrum for a [Ag-100/NiFeCo-20] multilayer, as obtained at normal incidence, with the corresponding bilayer thickness calculated at

FIG. 1. XRD spectra of single-layers, 2400 Å thick, NiFeCo films deposited at 3 and 7 mTorr—single phase fcc structures.

(115±5) Å. High angle scans of these samples were used to indirectly verify the repeatability of the thin NiFeCo layers. In Fig. 2 the corresponding high angle scan of the same sample is shown, in which the (111) line of the silver layer is observed along with its corresponding satellite peaks. A rather broad amorphouslike peak is observed over the (111) line region for NiFeCo, as would be expected from a 20 Å thin layer.

B. Magnetic data

The easy and hard axis H_c values were measured at an applied field of 50 Oe, with nominal values of 2 and 0.5 Oe, respectively, at thicknesses of 500 Å. Significantly lower values can be obtained at deposition rates higher than 15 Å/s; however, the nominal deposition rates for the films in this study are at a fraction of that, at 5 Å/s. A summary of the easy and hard axis coercivities evaluated over the entire

FIG. 2. Low angle and high angle XRD spectra of an [Ag-100/NiFeCo-20] multilayer signifying the periodicity of the constituent layers.

FIG. 3. Easy and hard axis coercivity data for the NiFeCo films, as deposited at 3 and 7 mTorr, plotted as a function of film thickness.

deposition range are shown in Fig. 3. The magnetic properties of the low end thickness films (i.e., 20 and 50 Å of NiFeCo) were determined from the same bilayer stacks used for the low angle XRD measurements. This allowed for noise elimination and more accurate determination of the particular magnetic properties. Interaction of the individual magnetic layers was prevented by the Ag interlayers, which were grown to adequate thicknesses for this purpose. However, the presence of silver interfaces may be the cause of the modified magnetic behavior in these films, which in this configuration lack the free surface of a single-layer film. Nevertheless, the choice was made so that the thinner layers could be evaluated with the available instrumentation. The coercivity response curve is highly nonlinear with thickness, in the range below 500 Å, for both 3 and 7 mTorr pressures. This behavior may be attributed to varying stages of growth dynamics that are characteristic for each of the thicknesses. However, in the high thickness range the properties were found in the same range as that expected for the bulk alloy. The values of the MR and anisotropy fields are following the same pattern as that of the coercivity curves (Fig. 4). That is, the higher anisotropy fields correspond to the lower MR values. Similar oscillatorylike behavior as a function of thickness, in the magnetic hysteresis and MR properties has been observed for NiFe films, with its origin attributed to quantum size effects.^{10,11} The magnetic data of the samples deposited at 7 mTorr are highly differentiated as compared with the results at 3 mTorr. The differences may be attributed to structural variations of the grains in the two pressure regimes. Although the deposition rate is not affected at the two different pressures for the same deposition power, it is the grain formation and gas adsorption that may be significantly changed as the pressure increases. The films grown at lower deposition pressure are denser with substantially lower coercivities.¹² At 7 mTorr the easy axis coercivities are much higher, as expected, with the higher corresponding anisotropy fields. The hard axis coercivities were found to deviate significantly at thicknesses above 1500 Å for the 7 mTorr films, with the deviation well above the experimental error

FIG. 4. The corresponding MR and H_k values for the NiFeCo samples of Fig. 3.

(better than 5%). The in-plane dispersion of the magnetic moments becomes significantly large for these highly anisotropic films, as shown in Fig. 6. The angle of dispersion at 90% saturation increases dramatically above 1500 Å, while it is $\leq 2^\circ$ for the thicknesses below 1500 Å. At 3 mTorr, α_{90} is $\leq 1^\circ$ as long as the film thickness remains below 2000 Å, and $\leq 2^\circ$ above that thickness range, as determined from the BH loop tracer measurements.

FIG. 5. Angle of dispersion at 90% saturation for the NiFeCo range of thicknesses studied.

FIG. 6. Saturation magnetization data as obtained at 500 Oe applied magnetic field, as a function of film thickness.

The saturation magnetization values were determined from VSM measurements and are shown in Fig. 6. The values of M_s for films thicker than 300 Å are essentially constant at 1050 ± 50 emu/cm³. For the thinner films, instrumental sensitivity limitations and experimental error (in addition to the possibility of modified magnetic behavior due to the multilayer configuration) may account for the deviation, since the XRD data did not indicate the presence of oxide peaks.

Ferromagnetism of $Y_2(Fe_{1-y}Co_y)_{17-x}Al_x$

N. Ohkubo and K. Kanematsu

The Physical Science Laboratories, Nihon University at Narashino, Funabashi, Chiba 274, Japan

Magnetization and x-ray measurements of alloy systems, $Y_2(Fe_{1-y}Co_y)_{17-x}Al_x$ ($y=1/3, 2/3$), were performed and the magnetic and crystallographic data are shown with the results of the systems where $y=0$ and 1.0 . The crystal structure of all alloys changes from hexagonal Th_2Ni_{17} type to rhombohedral Th_2Zn_{17} type with increasing aluminum concentration. The average magnetic moments of the $3d$ metal atom of all alloy systems decrease with increasing aluminum concentration. The Curie temperatures of the alloy systems where $y=1/3, 2/3$, and 1.0 decrease smoothly with increasing aluminum concentration. On the other hand, the system where $y=0$ at first increases and then decreases. These magnetic properties are discussed by Stoner's model. © 1996 American Institute of Physics. [S0021-8979(96)30508-7]

I. INTRODUCTION

The magnetization and Curie temperature of $Y_2Co_{17-x}Al_x$ decrease with increasing aluminum concentration. The Curie temperature as a function of the magnetic moment of cobalt qualitatively agrees with a relation predicted by Stoner's theory.^{1,2} The magnetization of $Y_2Fe_{17-x}Al_x$ similarly decreases with increasing aluminum concentration; however the Curie temperature increases with increasing aluminum concentration and turns to decrease.³⁻⁵ The aluminum concentration dependence of the Curie temperature is qualitatively explained by a localized moment model. Thus the magnetic properties of $Y_2Co_{17-x}Al_x$ and $Y_2Fe_{17-x}Al_x$ are explained by two extreme models. The purpose of this paper is to report the magnetic properties of alloys with an intermediate composition.

II. EXPERIMENTAL PROCEDURE

The alloys were prepared by arc melting a mixture of Y (99.9% pure), Fe (99.9% pure), Co (99.9% pure), and Al (99.9% pure), with each composition in an argon atmosphere. Arc melting was repeated several times. Then the alloys were sealed in an evacuated silica tube and annealed at 1200 K for 0.6 Ms (7 days). Magnetization measurements were carried out by a vibrating sample magnetometer in a magnetic field of 0.84 MA/m (10.6 kOe).

III. X-RAY AND MAGNETIZATION MEASUREMENTS

In the crystal structure of R_2T_{17} alloys, there are two types of structure: (1) a hexagonal Th_2Ni_{17} structure, which consists of two layers stacked in a hexagonal block with a composition of R_2T_{17} ; and (2) a rhombohedral Th_2Zn_{17} structure, which consists of three layers stacked in a hexagonal representation. There are four sites for T atoms in the hexagonal block; $T_1=6g$, $T_2=12j$, $T_3=12k$, $T_4=4f$ in the Th_2Ni_{17} structure and $T_1=9d$, $T_2=18f$, $T_3=18h$, and $T_4=6c$ in the Th_2Zn_{17} structure.

X-ray diffraction with Cu-K α radiation shows that all alloys without aluminum have a Th_2Ni_{17} structure. Substitution of aluminum for the transition metals weakens and ultimately leads to the disappearance of the characteristic line (221) of the Th_2Ni_{17} structure. Further substitution of alumi-

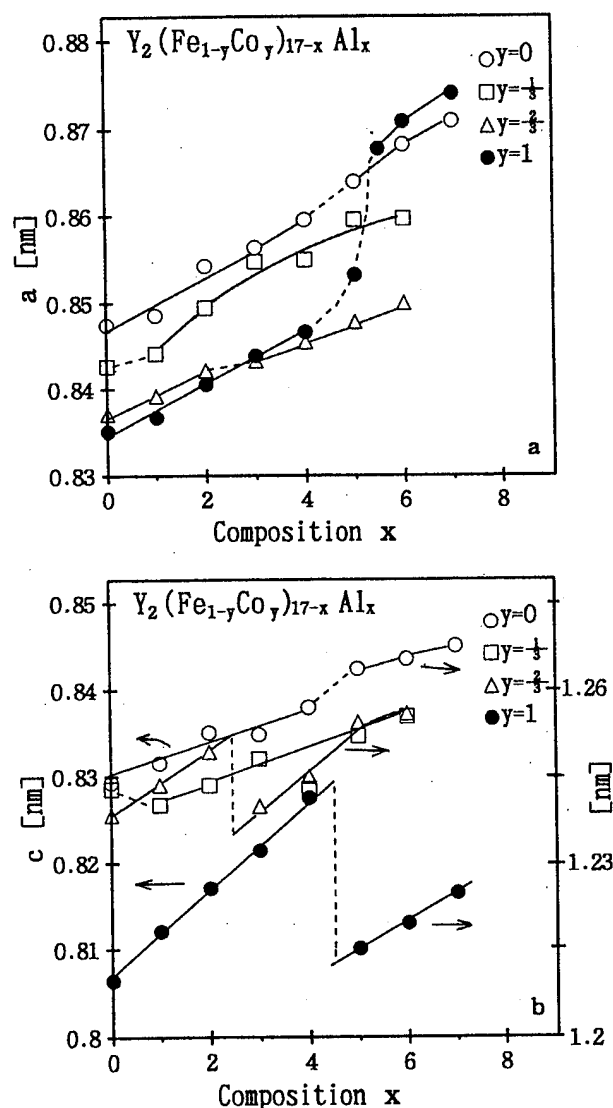

FIG. 1. Lattice constants of $Y_2(Fe_{1-y}Co_y)_{17-x}Al_x$ ($y=0, 1/3, 2/3, 1.0$) are plotted for the aluminum concentration x . Structural changes from hexagonal Th_2Ni_{17} type to rhombohedral Th_2Zn_{17} type (represented hexagonal structure) occur at $4 < x < 5$ for $y=0$, $0 < x < 1$ for $y=1/3$, $2 < x < 3$ for $y=2/3$, and $4 < x < 5$ for $y=1.0$: (a) Lattice constants a ; (b) lattice constants c .

FIG. 2. Thermomagnetic curves of $Y_2(Fe_{2/3}Co_{1/3})_{17-x}Al_x$ measured in a magnetic field of 10.6 kOe.

num leads to the appearance of and subsequently strengthens the characteristic line (104) of the Th_2Zn_{17} structure. The structural change from Th_2Ni_{17} to Th_2Zn_{17} occurs at $4 < x < 5$ in the alloy system where $y=0$, at $0 < x < 1$ in the system where $y=1/3$, at $2 < x < 3$ in the system where $y=2/3$, and at $4 < x < 5$ in the system where $y=1$. The lattice constants of the alloys are shown in Fig. 1.

The thermomagnetic curves of alloys in two alloy systems, where $y=1/3$ and $2/3$, are shown in Figs. 2 and 3, respectively. The compositional dependencies on magnetization and Curie temperature of both alloy systems are shown with the results of the $Y_2Co_{17-x}Al_x$ and $Y_2Fe_{17-x}Al_x$ systems in Figs. 4 and 5, respectively. The structural change induces the changes in the compositional dependencies on magnetization and Curie temperature of each alloy system.

FIG. 3. Thermomagnetic curves of $Y_2(Fe_{1/3}Co_{2/3})_{17-x}Al_x$ measured in a magnetic field of 10.6 kOe.

FIG. 4. Magnetizations σ of $Y_2(Fe_{1-y}Co_y)_{17-x}Al_x$ ($y=0, 1/3, 2/3, 1.0$) at 0 K, expressed in terms of Bohr magneton per formula unit $[Y_2(Fe_{1-y}Co_y)_{17-x}Al_x]$, are plotted for aluminum concentration x . The dotted lines show the composition of structural change from Th_2Ni_{17} type to Th_2Zn_{17} type.

IV. ANALYSIS BY STONER'S MODEL

The decreasing rates of magnetization per formula unit $Y_2(Fe_{1-y}Co_y)_{17-x}Al_x$ ($y=1/3, 2/3$) due to the substitution of aluminum for the transition element (Fe, Co) are $3.5 \mu_B/f.u.$ ($y=0$), $3.6 \mu_B/f.u.$ ($y=1/3$), and $2.1 \mu_B/f.u.$ ($y=2/3$) at $0 < x < 3$, $4.5 \mu_B/f.u.$ ($y=2/3$) at $3 < x$, and $3.9 \mu_B/f.u.$ ($y=1$). According to the band model, the energies of the $3d$ upspin subband and $3d$ downspin subband are separated by an exchange interaction, and the net magnetic moment of the $3d$ metal arises from the excess population. A simple band theory tells us that the valence electrons of aluminum transfer to the unfilled $3d$ and $4s$ band of the $3d$ metal and

FIG. 5. Curie temperatures T_c of $Y_2(Fe_{1-y}Co_y)_{17-x}Al_x$ ($y=0, 1/3, 2/3, 1.0$) are plotted for the aluminum concentration x . The dotted lines show the composition of structural change from Th_2Ni_{17} type to Th_2Zn_{17} type.

FIG. 6. Average magnetic moments of the 3d metal atom, $\sigma_a = \sigma / (17-x)$, are plotted for Curie temperature T_C . Solid lines are theoretical curves obtained by the Stoner model with a parabolic band.

that the decreasing rate of magnetization due to the substitution is equal to or less than $3.0 \mu_B$. However, most of the experimental data are larger.

A second interpretation is that the aluminum atoms surrounding the 3d metal atom weaken the exchange interaction and make the net magnetic moment decrease. According to this model, the spontaneous magnetization of alloys occurs in incomplete saturation. This is discussed in Stoner's theory.⁶ This theory suggests that the ferromagnetism of $Y_2(Fe_{1-y}Co_y)_{17-x}Al_x$ ($y=1/3, 2/3, 1.0$) is in incomplete saturation and that an increase of the interaction energy $k\theta'$ leads to an increase of the magnetization and Curie temperature. Figure 6 shows the Curie temperature curves of every alloy system plotted as functions of the average magnetic moments of the 3d metal atom (Fe and Co) σ_a with the alumi-

num concentration as the implicit parameter. The average magnetic moments σ_0 are obtained from the magnetizations σ by assuming that the yttrium and aluminum have no magnetic moment. The solid lines are curves calculated from Stoner's theoretical curves of kT_C/ϵ_0 vs σ_0/σ_{a0} ,⁶ where T_C is the Curie temperature and σ_{a0} is the average magnetic moment in complete saturation. The values of ϵ_0 and σ_{a0} used in the theoretical curves are $\sigma_{a0}=2.30 \mu_B$ and $\epsilon_0=2210$ K for the alloy system of $Y_2(Fe_{1-y}Co_y)_{17-x}Al_x$ where $y=1/3$, $\sigma_{a0}=1.94 \mu_B$ and $\epsilon_0=2570$ K for the system where $y=2/3$, $\sigma_{a0}=1.68 \mu_B$ and $\epsilon_0=3870$ K for the system where $y=1.0$ with a Th_2Ni_{17} structure and $\sigma_{a0}=1.68 \mu_B$ and $\epsilon_0=5150$ K for the system where $y=1.0$ with a Th_2Zn_{17} structure. Assuming that the net magnetic moment comes from the hole of the 3d band, the values of σ_{a0} and the magnitude of ϵ_0 are reasonable. The agreement between the experimental values and theoretical curves is very good even though the Stoner model is a simple theory that neglects the band structure and other important factors. The effect of aluminum on the interaction energy is estimated from the theoretical curve of $k\theta'/\epsilon_0$ vs σ_0/σ_{a0} , and the rate of decrease of $k\theta'/\epsilon_0$ with the addition of one aluminum atom is 0.014–0.018.

The decrease of the average magnetic moment of iron with increasing aluminum concentration in $Y_2Fe_{17-x}Al_x$ suggests that the magnetism of this system is an itinerant electron magnetism, but it is not easy to interpret the aluminum concentration dependence on Curie temperature by an itinerant electron model like Stoner's theory.

Y. Yamaguchi

Institute for Materials Research, Tohoku University, Sendai, Japan

Cubic Laves phase alloy YFe_2 forms four types of hydrides, YFe_2H_x : β_1 , β_2 (hexagonal) of $1.2 < x < 1.6$, γ (hexagonal) of $2.8 < x < 3.45$, and δ (orthorhombic) of $3.7 < x$. The β_1 and β_2 hydrides are formed in the hydrogen absorption below and above 500 K.¹ The deuterides YFe_2D_x have been prepared by deuterium absorption at various temperatures for YFe_2 powders of diameters less than 0.3 mm. The formed samples are mixtures of main and extra deuteride phases. The x-ray and magnetization measurements in a magnetic field of 10.6 kOe showed five types of ferromagnetic deuterides with Curie temperatures of about 100 K (δ_1), 300 K (δ_2), 380 K (γ), 300–380 K (β_1), and 540 K (amorphous). The extrapolated values of magnetization at 0 K are $3.5\mu_B/\text{YFe}_2\text{D}_x$. The crystal structures are as follows: δ_1 , hexagonal, $a=0.57$ nm, $c=2.74$ nm; δ_2 , cubic, $a=0.79$ nm; γ , hexagonal, $a=0.56$ nm, $c=2.63$ nm; and β , hexagonal ($a=0.53$ nm, $c=0.87$ nm)–($a=0.51$ nm, $c=0.82$ nm). © 1996 American Institute of Physics.

Hydrogen charging in nickel and iron and its effect on their magnetic properties

A. Ramesh, M. R. Govindaraju, D. C. Jiles, S. B. Biner, and J. M. Roderick
Department of Materials Science and Engineering, Iowa State University, Ames, Iowa 50011

The current study was undertaken to explore the possibility of detecting hydrogen cavitation in magnetic materials through magnetic property measurements. It is known that dissolved hydrogen in a material causes microvoids. These voids may affect the structure-sensitive magnetic properties such as coercivity and remanence. In this study, hydrogen was introduced into nickel and iron by two processes, namely thermal charging and cathodic charging. The effect on the magnetic properties was measured. In addition, the variation of the magnetic properties with porosity was studied. © 1996 American Institute of Physics. [S0021-8979(96)30608-3]

I. INTRODUCTION

The presence of hydrogen in metals is known to have a significant impact on the mechanical properties.¹ Generally, hydrogen is taken up in interstitial sites, but at higher concentrations it can lead to the formation of voids. Oriani² has confirmed that the exact nature of hydrogen dissolved in a metal is that of a proton which has given up its electron to the electron gas of the metal. The solubility of hydrogen in nickel and iron is proportional to the square root of the external hydrogen pressure, at least for small concentrations according to Sieverts.³ Also the diffusion of hydrogen through a metal follows the Arrhenius equation and is therefore much faster at higher temperatures. Lord⁴ has suggested that hydrogen is more likely to reside in octahedral rather than the tetrahedral sites in iron.

When hydrogen is introduced into a lattice at high temperature and pressure and the material is then quenched back to ambient conditions, the lattice is no longer capable of retaining all of the hydrogen. The excess hydrogen is taken up by internal traps such as dislocations, grain boundaries, and vacancies. Thus the physical picture is that of hydrogen dissolved in the lattice with the excess amount residing in internal voids. The presence of dissolved hydrogen in a metal causes an expansion of its lattice. Smialowski⁵ concluded that the irreversible external dimensional changes of iron samples caused when they are charged with hydrogen, are due to molecular hydrogen gas at very large pressures. However, detection of hydrogen in a material is very difficult due to its extremely small equilibrium lattice solubility of only 5×10^{-10} at normal temperature and pressure.

In a ferromagnetic material, the process of magnetization occurs by the movement of the domain walls. This motion can be hindered by the presence of pinning sites such as second phase particles and inclusions resulting in hysteresis. According to the model of Kersten and Neel,^{6,7} the presence of nonmagnetic inclusions or voids causes pinning of magnetic domain walls and leads to an increase in the coercivity and a decrease in permeability. Baum⁸ noted that the structure-sensitive properties such as coercivity and permeability appear to be dependent on the porosity of iron. More recently, Jiles *et al.*⁹ have reported that the coercivity of iron is at maximum when the pores have a diameter of about 8–11 μm .

Oriani and Josephic¹⁰ studied the effect of hydrogen on the plastic deformation of steel and reported that the basic effect is an increase in the population of the microvoids at a given strain. Hydrogen of very high fugacity nearly doubles the microvoid population. This causes an increase in the number of voids present in the material which acts as pinning sites, thus leading to changes in its magnetic properties. In addition, the presence of hydrogen causes local strain in the material, which also impedes the motion of the domain walls as suggested by Becker.¹¹ In view of these effects, an attempt has been made in the present work to study the effect of hydrogen on the magnetic properties of materials based on iron and nickel.

II. EXPERIMENTAL PROCEDURE

Hydrogen can be introduced into the metal in several ways. These include thermal charging, cathodic charging, and acid corrosion.¹² Of these methods the first two were used in the present work and the change in the magnetic properties was studied.

A. Thermal charging

Pure nickel rods of 10 mm diameter and 100 mm length were put in a chamber which was evacuated and then subjected to a pressure of 100 atm of hydrogen at 500 °C. The maximum solubility of hydrogen under these conditions was calculated as 0.0015 atoms of H_2 /atom of nickel. The time taken for saturation of hydrogen was 2.5 h. During charging, the samples were subjected to hydrogen charging for different periods of time, causing varying uptakes of hydrogen. Baseline magnetic measurements were taken after annealing the sample at 500 °C for 12 h. Magnetization measurements were made using a magnetic hysteresisgraph. Results were analyzed using a software package written exclusively for the experimental system.

B. Cathodic charging

Cathodic charging has often been used to introduce hydrogen into metals because of its convenience and its ability to produce high fugacity of hydrogen. This is an electrolytic process in which hydrogen is charged into the metal cathodically using platinum wire as the anode. Boniszewski and Smith¹³ have used this method to study the effect of hydro-

FIG. 1. Variation of coercivity of iron as a result of cathodic charging.

gen in the plastic deformation of nickel. In the current study charging was done in a 1 N sulfuric acid bath at room temperature with a current density of about 500 A/m^2 for different times. Thiourea was used as the catalyst, causing a hydrogen input fugacity of 10^7 MN/m^2 . The magnetic properties were measured as a function of the amount of hydrogen in the sample. These are shown in Fig. 1.

III. RESULTS AND DISCUSSION

A. Thermal charging

The results of thermal charging are shown in Fig. 2. Initially, the coercivity and remanence decreased as expected, since a large number of dislocations and stress fields which act as pinning sites for the domain walls are removed as a result of annealing. Upon charging to 100 atm of hydrogen at 500°C , the magnetic properties varied due to both the addition of hydrogen and exposure to high temperature which further relieved the residual stress. During the initial stages of charging, the main effect was simply the annealing of residual stress, thus the coercivity decreased. However, as the hydrogen content increased, it caused an increase in the density of voids and resulting internal stress and led to an increase in the coercivity. Quantitatively, the changes due to

FIG. 2. Variation of coercivity and remanence of nickel as a result of thermal charging.

hydrogen charging were small, amounting to a maximum of 0.5 Oe. The small changes in the magnetic properties resulted from a low hydrogen intake which resulted in a small number of additional voids formed. Also, the excess hydrogen was preferentially chemically adsorbed on to inclusions and grain boundaries which acted as pinning sites even in the absence of hydrogen.¹ In these cases, the number of new pinning sites introduced by the hydrogen absorption would be small, leading to only a small increase in coercivity.

B. Cathodic charging

Hydrogen introduced by charging may affect the magnetic properties of iron-based alloys either by the formation of hydrides or by the formation of voids. Kimura and Birnbaum¹⁴ have reported observations using transmission electron microscopy of small gas bubbles in iron cathodically charged at 20 A/m^2 which caused blisters to form due to the high pressure of hydrogen. According to Boniszewski and Smith,¹³ hydrides could be formed on the surface layers of the material under certain charging conditions. It has also been reported in the literature that the thickness of the hydride layer formed on the surface by cathodic charging at room temperature for 48 h was as small as $10 \mu\text{m}$. The high fugacity of hydrogen, and the corresponding high hydrogen concentration gradients, may therefore affect only the surface layers of the specimen. This has also been confirmed by Kimura and Birnbaum.¹⁴ While cathodic charging of relatively thick specimens had relatively little effect on their measured flow stress, large effects were observed for smaller specimens with diameters of 0.1 mm or less. Thus it is established that the effect of hydrogen on the magnetic properties is entirely a surface phenomena. The measured hysteresis properties were however averaged values over the bulk sample and therefore these magnetic properties do not exhibit significant changes due to the addition of hydrogen.

IV. EFFECT OF POROSITY

In order to confirm these conclusions concerning the effect of hydrogen on the magnetic properties, it was decided to study the effect of uniformly distributed pores on the mag-

FIG. 3. Variation of coercivity and remanence with the density of nickel specimens with controlled amounts of porosity.

netic properties of pure nickel. For this purpose, pure nickel rods with different levels of porosity were prepared and their magnetic properties were studied. Compacts were made using nickel powder mainly composed of individual particles that were typically a few microns in diameter. The compacts were cold isostatically pressed by applying a pressure of 4400 atm and sintered under different conditions to obtain different densities. The four compacts thus obtained were tested for their magnetic properties at room temperature. From the data plotted in Fig. 3, it can be seen that there was a regular decrease in some of the magnetic properties such as the coercivity and remanence, as the density increased. This is because the number of pores decreases as the density increases and these act as the pinning sites for the motion of the domain walls. As a result, the irreversible nature of the magnetization was enhanced and therefore the coercivity, remanence, and hysteresis loss increased at low densities.

V. CONCLUSIONS

Hydrogen absorption in nickel under extreme conditions of high temperature and pressure had a small effect on the bulk magnetic properties, since the hydrogen does not form new pinning sites, but is adsorbed on those that already exist. The largest measured change in coercivity was from 2.0 to 1.5 Oe. Cathodic charging of nickel or iron resulted only in changes to the surface from the formation of hydrides or voids and this did not greatly affect the bulk magnetic properties. In this case the largest change in coercivity was from

2.6 to 1.6 Oe. The presence of voids in the bulk of the material affected the magnetic properties and can be related directly to the density of the material. These results led to the conclusion that the detection of hydrogen by bulk magnetic measurements is problematic unless the amount of hydrogen is very high, the hydrides can be formed in the bulk material, or the resolution of the magnetic measurements is sufficiently high.

Magnetic viscosity investigations of nanograin iron powder

U. Atzmony,^{a)} Z. Livne,^{a)} R. D. McMichael, and L. H. Bennett
National Institute of Standards and Technology, Gaithersburg, Maryland 20899

Magnetic properties of three kinds of nanograin Fe powder were studied. The first two, designated as NM(Ar) and NM(N), were obtained by ball milling the iron powder under an argon or nitrogen atmosphere. The third, designated NN, was obtained by evaporation and condensation. They have grain sizes of 20, 7, and 60 nm, respectively. The particle sizes of the first two were in the micrometer range, whereas those of the NN were in the nanometer range. The NN powder exhibited a coercivity of 79 mT; its magnetic moment at saturation was lower than that of bulk iron. The coercivities of the NM(N) and NM(Ar) were much smaller and their magnetic moment values at high fields were closer to that of bulk iron ($210 \text{ A}\cdot\text{m}^2/\text{kg}$). The NM(N) and NN samples exhibited marked time dependences of the magnetic moments following a relatively abrupt change of the applied field. The moment changes by more than 0.5% of the saturation moment within 50 min and continues to change for many hours. Much smaller effects were detected in the NM(Ar) sample. The viscosities were investigated as a function of temperature and jump field. The results showed differences in the behavior of the three samples. The powders were consolidated by cold isostatic pressing followed by sintering at around 600 °C for several hours. The magnetic behavior of the sintered samples approach that of bulk iron. © 1996 American Institute of Physics. [S0021-8979(96)30708-X]

I. INTRODUCTION

Ultrafine ferromagnetic particles are of technological interest for magnetic fluids, magnetic recording media, permanent magnets, and catalysts. Viscosity effects were always detected in either alloys or layered samples. This article represents the first time that this effect was detected and investigated in elemental samples.

The magnetization, M , of a hysteretic magnetic material in a steady applied field is often well described by a logarithmic time dependence,

$$M = M_0 - S \cdot \ln(t/\tau). \quad (1)$$

The magnetic viscosity, S , is a consequence of thermally excited irreversible processes, and has been shown to be related to the irreversible susceptibility, χ_{irr} , by

$$S = k_B T \frac{\chi_{\text{irr}}}{(\partial E_b / \partial H)}, \quad (2)$$

where E_b is the height of the energy barrier.¹

II. EXPERIMENT

Three iron powder samples, designated as NM(N), NM(Ar), and NN, were investigated. The first letter in the name symbolizes the grain size (N suggests nanometer size and M, micrometer) and the second letter, the particle size. Sizes were provided by the producers^{2,3} and checked by us: grain sizes were derived from x-ray analysis and particle

sizes from SEM (see Table I). The NM powders were made by ball milling iron under N or Ar atmospheres, respectively,² while the NN was prepared by evaporation and condensation.³ Room temperature Mössbauer studies revealed the existence of $\approx 5\%$ oxidized phase (apparently Fe_3O_4) in the NN powder samples. Because this powder is not pyrophoric, we believe that this oxide phase forms a coating on the particles. No oxide was observed by Mössbauer in the NM powder samples.

In addition to these "as received" powders, magnetic measurements were made on powders consolidated by cold isostatic pressing (CIP) followed by sintering at 580 and 850 °C for several hours. Mössbauer measurements showed that the amount of oxidized phase increased to $\approx 20\%$ during the consolidation and heat treatment.

Magnetic properties were studied mainly using a DC extraction magnetometer. In this technique, the flux change is detected as the sample is removed from a sensing coil within a superconducting magnet. In several instances, measurements were also taken with a SQUID magnetometer.

The time dependence was measured using the following protocol: After reaching the desired temperature under zero field, the field was set to 0.8 T. Then, under computer control, the field was reset to a value H_2 , $H_2 < 0.8 \text{ T}$. It took $\approx 50 \text{ s}$ for the field to stabilize. After the reset value of the field was stabilized, the magnetization was recorded as a function of time for up to 4 days. The time behavior was linearly best fitted to $M = M_0 + S \cdot \ln(t)$, where the slope, S , was defined as the magnetic viscosity or after effect.

TABLE I. Sizes and impurities in powder samples.

Powder	Grain size nm from Refs. 2 and 3	X-ray	Particle size μm from Refs. 2 and 3	SEM	[O] weight %	[N] weight %
NM(N)	5–6.5	7.8	4–27	1–10	2.45 ± 0.25	1.15 ± 0.05
NM(Ar)	11–13.5	23	4–27	1–10	2.46 ± 0.05	0.11
NN	...	60	0.1–0.2	0.06	5.7	0.005

III. RESULTS AND DISCUSSION

Major and minor hysteresis loops of the three powder samples and that of consolidated NM(N) and NN were recorded at various temperatures between 5 and 300 K. Examples of major loops are shown in Fig. 1. The loops exhibited striking differences between one another and between bulk metallic iron. The powder NN sample has the widest loop (coercivity, $H_c = 79$ mT at 5 K) and the smallest saturation magnetization, M_s . The value of M_s at 5 K ($205 \text{ A}\cdot\text{m}^2/\text{kg}$) for the NM(Ar) powder sample was very near to that of metallic iron ($210 \text{ A}\cdot\text{m}^2/\text{kg}$). These results do not agree in detail with some published data.⁴ Consolidation of the powders shifts the hysteresis loops towards that of metallic iron; namely, the coercivity is reduced and the value of M_s increases for the consolidated sample compared to the relevant powder ones.

The temperature behaviors of the NM(N) and NN powder samples were derived both from the different hysteresis loops, and from direct measurements of M versus T at various fields. The coercivity of the NM(N) powder sample showed a maximum (≈ 8 mT) near 30 K. It then decreased with increasing temperature to ≈ 6 mT and remained at this value up to 300 K. The coercivity of the NN powder monotonically decreased with concave behavior from 79 mT at 5 K to 60 mT at 300 K.

Magnetic after effects were measured for different jump fields H_2 , for the three powder samples at different temperatures. An example is given in Fig. 2, where the results for a bulk Fe alloy is shown for comparison. Following the protocol described in the experimental section, the field was abruptly changed from 0.8 T to a smaller value H_2 . The value of the magnetic moment thus decreases, and when H is stabilized, the moment is near the value obtained directly from the hysteresis loop. With time, this value continues to

decrease and the change continues for many days. The NM(N) and NN samples exhibited distinctive time effects with the slopes reaching values of $\approx -0.1 (\text{A}\cdot\text{m}^2/\text{kg})/\ln(s)$, i.e., changes of around $1 \text{ A}\cdot\text{m}^2/\text{kg}$ in 3000 s. The maximum total changes due to time effects are $\approx 0.5\%$ to 1% of the value of the magnetic moment at high fields. In the NM(Ar) sample, the effect was very small, less than 0.05% of the value of the magnetic moment, and thus, detailed investigations of time effects were limited to the NM(N) and NN samples. No changes were detected for the bulk iron sample. This excludes an assumption that the drifts reflect a drift of the superconducting magnet.

When we previously explored the time effect phenomenon in multilayer systems,⁵ we found that the magnitude of the effect reached a maximum for jump field values near the reverse coercivity, and decreased in magnitude to both sides in an approximately Lorentzian shape. Similar behavior was observed here with the NN sample. At 5 K, the maximum was obtained around -79 mT, the negative coercive force, with a Lorentzian width of ≈ 50 mT. But the slope values, for fields which were more than twice the width from the center, departed from the Lorentzian behavior by decreasing more slowly. Better agreement with a Lorentzian behavior was obtained for 80 K (Fig. 3). At 80 K, the coercivity was ≈ 70 mT, but the maximum value of $|S|$ was obtained at -110 mT, with a width of ≈ 80 mT. The maximum thus appears to be closer to the maximum of dM/dH , which occurs at ≈ -100 mT, than to the coercivity.

The behavior of the H_2 dependence of S in the NM(N) sample is quite different. Both the NN and the NM(M) samples showed increases of $|S|$ between 5 and 30 K, but for the NN sample, the slope was almost insensitive to tempera-

FIG. 1. Hysteresis loops of the three nanograin powders at 5 K.

FIG. 2. Magnetic after effect in three nanograin Fe powders, and in bulk steel. The magnetization decay after a field jump from 0.8 T to -30 mT at 5 K is shown as a function of the time after the jump.

FIG. 3. Slopes of the decay of the magnetization for the NN Fe powder at 80 K after a jump from 0.8 T to the jump fields shown. Each data point represents a best linear fit to a magnetization vs \ln time after the jump.

tures above 30 K. In contrast, the NM(N) slope values reached a maximum at this temperature, and then decreased as the temperature was raised to 300 K (Fig. 4). A similar decrease is seen for the value of S at differing values of H_2 , two of which are shown in Fig. 4. The decrease from the maximum value is more rapid for jump fields which are greater than H_c , which is ≈ 8.5 mT. The maximum of dM/dH is near zero.

At 30 K (see Fig. 5), the NM(N) sample exhibited a "square"-like maximum for H_2 between -50 and -200 mT, with the negative field side decreasing in a Lorentzian behavior, and the positive field side fitting a Gaussian function. More detailed examination of the effects of demagnetizing factor and of the irreversible susceptibility are underway.

In many discussions of magnetic viscosity, it was found that the time behavior of the magnetic moments best described as a linear dependence on the logarithm of the time,⁵ and the slope for a best fit to such behavior was the measure for our reported time effects. To check this statement more thoroughly, several time dependence measurements, at values for which relative high slopes were obtained, were carried for a longer period of time up to 14 h. The lines were then fitted to the logarithmic behavior. The agreement be-

FIG. 4. Slopes of magnetization vs \ln time for the NM(N) Fe powder plotted vs temperature. Two of the curves are for the untreated powder, with jump fields of -30 and -5 mT. The other two curves are for the same powder after sintering at 580 and 850 °C, with jump fields of -5 mT.

FIG. 5. Slopes of the decay of the magnetization for the NM(N) Fe powder at 30 K after a jump from 0.8 T to the jump fields shown.

tween the fit for this longer time and the results for a duration of 3000 s was very good; the NM(N) was exceptionally good. For longer times with the NN sample, the change of magnetic moment was faster than the logarithmic behavior; i.e., the slopes at the longest times are larger. For even longer times, the fit was quite good again; i.e., the real behavior "rotated" around the best fit.

For both samples, the slopes were drastically decreased after consolidation. As an example, Fig. 4 shows two consolidated NM(N) samples, one at 580 °C for 3 h and one at 850 °C for 3 h. Both samples exhibited similar jump field and temperature dependencies, with a minimum at 30 K and with a wide jump field dependence between -100 and 100 mT.

IV. SUMMARY

The magnetic viscosity was measured in three types of nanograin powders of iron. The low values of S in the NM(Ar) powder, along with its low coercivity, suggest that irreversible processes are weak in this sample. The NM(N) sample showed a maximum in $|S|$ near 30 K; the NN had an approximately flat behavior from 300 to 30 K. These results need to be discussed in terms of particle switching, particularly for the NN, and weak domain wall pinning,⁶ particularly for the NM(N). The broad distribution of S versus H_2 (Fig. 5) remains a mystery.

Magnetic properties and the crystallization of amorphous $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$

Chul Sung Kim and Sung Baek Kim

Department of Physics, Kookmin University, Seoul 136-702, Korea

J. S. Lee and T. H. Noh

Division of Metals, Korea Institute of Science and Technology, Seoul 130-650, Korea

The amorphous state of ferromagnetic $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ and its nanocrystallization have been studied by x-ray, Mössbauer spectroscopy, and magnetic moment measurements. In the amorphous state at 13 K, the Mössbauer spectrum exhibits an essentially symmetric hyperfine field distribution with a half-width of 72 kOe. The average hyperfine field $H_{\text{hf}}(T)$ of the amorphous state shows a temperature dependence of $[H_{\text{hf}}(T) - H_{\text{hf}}(O)]/H_{\text{hf}}(O) = -0.48(T/T_C)^{3/2} - 0.22(T/T_C)^{5/2}$ for $T/T_C < 0.7$, indicative of spin-wave excitation. The quadrupole splitting just above the Curie temperature T_C is 0.43 mm/s, whereas the average quadrupole shift below T_C is zero. The Curie and crystallization temperatures are determined to be $T_C = 393$ K and $T_x = 775$ K, respectively, for a heating rate of 5 K/min. The occupied area of the nanocrystalline phase at the optimum annealing temperature is about 33%–71%. It is notable that the magnetization of the amorphous phase decreases more rapidly with reduced temperature than those of nanocrystalline ferromagnets, suggesting the presence of the distribution of exchange interactions in the amorphous phase or high metalloid contents. © 1996 American Institute of Physics. [S0021-8979(96)30808-6]

I. INTRODUCTION

Fe-based amorphous ferromagnets like Fe–Si–B–Cu–Nb¹ and Fe–B–Cu–(Zr,Hf,Nb)^{2,3} are improved by annealing above the crystallization temperature T_x . This improvement is caused by the precipitation of α -Fe in the amorphous matrix. Ferromagnetic nanocrystalline phases, produced by the crystallization of an amorphous phase, display a high initial magnetic permeability and a low coercivity.⁴ The average magnetic hyperfine field measured at the Fe sites of a number of glassy ferromagnets has been reported to decrease more rapidly with increasing temperature than that of crystalline Fe. In particular, the glassy $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ has been researched and it exhibits a combination of remarkable soft magnetic properties.² After properly annealing at 830 K the material becomes an ultrafine grain structure (10 nm) of α -Fe embedded in a residual amorphous phase.

In this work, a study of the development of the nanocrystalline phase in the $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ alloy using Mössbauer spectroscopy is presented. When properly analyzed, Mössbauer spectra can yield magnetic information not easily obtained by other methods. The amorphous and crystalline volume fractions have also been determined. The magnetic and crystallographic properties are studied using Mössbauer spectroscopy, x-ray, and vibrating sample magnetometer techniques.

II. EXPERIMENT

Ultrathin $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ amorphous ribbons were fabricated by a single-roll melt-spinning method at pressures of 10^{-3} – 10^{-5} Torr. The conditions for producing ultrathin ribbons were a roll speed of 40–60 m/s, an ejection pressure of 0.005–0.02 kg/cm², and a rectangular slit of 0.15×4 mm. The ribbons obtained were 7–12 μm in thickness and 2–4 mm in width. The ribbons were wound into a toroidal core with a 21 mm inner diameter and subsequently annealed at 530 °C for 1 h. The Mössbauer spectra were recorded using a

conventional spectrometer of the electromechanical type⁵ with a ⁵⁷Co source in a rhodium matrix. The low temperature was obtained using an APD CS-202 dispex closed-cycle refrigeration system with a DMX-20 Mössbauer vacuum shroud interface, and the temperature controller was a model DRC-91 C manufactured by Lake Shore Cryotronics, Inc.

III. RESULTS AND DISCUSSION

Mössbauer spectra of the as-quenched amorphous $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ below the Curie temperature T_C exhibit broadened six-line patterns as shown in Fig. 1. The broad

FIG. 1. Mössbauer spectra of amorphous $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ at various temperatures.

FIG. 2. Fractional change of the magnetic hyperfine field, H_{hf} , as a function of $(T/T_c)^{3/2}$.

lines are to be expected in view of the disordered atomic arrangements, in which the strength of the hyperfine interactions changes from site to site due to the structurally inequivalent Fe environments. In the amorphous $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ at 13 K, the Mössbauer spectrum exhibits an essentially symmetric hyperfine field distribution with a half-width of 72 kOe by the Vincze⁶ model.

Figure 2 shows the fractional change of the magnetic hyperfine field, $[H_{hf}(T) - H_{hf}(0)]/H_{hf}(0)$, as a function of T . For most amorphous ferromagnets investigated so far, the magnetic hyperfine field decreases with increasing temperature as defined below,⁷

$$\frac{H_{hf}(T) - H_{hf}(0)}{H_{hf}(0)} = -B_{3/2} \left(\frac{T}{T_c} \right)^{3/2} - C_{5/2} \left(\frac{T}{T_c} \right)^{5/2}. \quad (1)$$

A least-squares fit of Eq. (1) to the magnetic hyperfine field data gave $B_{3/2} = 0.48 \pm 0.05$ and $C_{5/2} = 0.22 \pm 0.05$. This value of $B_{3/2}$ for the amorphous ferromagnet $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ is much larger than those of crystalline ferromagnets^{8,9} such as α -Fe and Ni; $B_{3/2} = 0.12$ for Ni and $B_{3/2} = 0.11$ for α -Fe. At low temperatures the values of the magnetic hyperfine field $H_{hf}(T)$ show a $T^{3/2}$ dependence that is related to the preferential excitation of long wavelength spin waves. The $T^{3/2}$ coefficient is about four times as large as those of crystalline Fe or Ni. So, more spin waves having long wavelengths are excited in amorphous ferromagnets than in crystalline ferro-

FIG. 3. Counts measured for 10 s at zero Doppler velocity as a function of temperature for $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$.

magnets. The quadrupole splitting just above the Curie temperature T_c is 0.43 mm/s, whereas the average quadrupole shift below T_c is zero.

In order to determine the Curie temperature T_c and the crystallization temperature T_x , the velocity transducer of the Mössbauer spectrometer was set at zero velocity and counts were recorded for a fixed counting time, 10 s, while the temperature was raised at a rate of 5 K/min from 293 to 850 K. The results are shown in Fig. 3. From the graph the Curie temperature is determined to be 393 K. As the temperature was further increased, the count rate increased slowly due to the second-order Doppler effect, and then increased suddenly at 775 K. After the amorphous $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ has reached the crystallization temperature $T_x = 775$ K, the amorphous state gradually transformed into the microstructure of the nanocrystalline phases.

Figure 4 shows Mössbauer spectra of the amorphous $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ taken above the crystallization temperature. In contrast to Fig. 1 for the amorphous phase, the Mössbauer spectra consists of six absorption lines (α -Fe phase) and a quadrupole doublet (amorphous phase). The occupied area ratio of the α -Fe phase at 780 K is 33%. Mössbauer spectra of an amorphous $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ furnace annealed at 830 K for 1 h are shown in Fig. 5. The analysis of the Mössbauer spectra shows that nanocrystalline $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ yields two phases. The corresponding hyperfine parameters are given in Table I. The nanocrystalline $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ showed 49%

TABLE I. Mössbauer parameters for amorphous $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ after annealing at 830 K for 1 h. H_{hf} is the magnetic hyperfine field, ΔE_Q is the quadrupole splitting, δ is the isomer shift and area ratio of α -Fe at various temperatures.

T (K)	Phase	H_{hf} (kOe)	ΔE_Q (mm/s)	δ (mm/s)	Area ratio (%)
13	α -Fe	342	0.00	0.01	48
	Amorphous	233	0.00	0.01	52
77	α -Fe	340	0.00	0.00	47
	Amorphous	225	0.00	0.01	53
293	α -Fe	329	0.00	-0.01	49
	Amorphous	150	0.01	-0.01	51

α -Fe and 51% amorphous at room temperature. The occupied area of the α -Fe phase at the optimum annealing temperature at around 900 K is about 71%.

The magnetic moment of the amorphous $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ has been measured at $H_{\text{app}} = 8$ kOe at various temperatures from the liquid-nitrogen temperature to the Curie tempera-

FIG. 5. Mössbauer spectra of annealed $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ at low temperatures.

FIG. 6. Reduced magnetization and hyperfine field vs reduced temperature of the amorphous $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$ and the crystalline phases after crystallization.

ture of the sample. The results are shown in Fig. 6 in reduced units along with the magnetic hyperfine fields obtained from the Mössbauer spectra. From Fig. 6, it is evident that the magnetic moment is proportional to the magnetic hyperfine field in the amorphous $\text{Fe}_{83}\text{B}_9\text{Nb}_7\text{Cu}_1$. The saturation magnetization of the as-quenched amorphous material extrapolated to 0 K is found to be $2.01 \mu_B/\text{Fe}$ atom. This value is smaller than the $2.22 \mu_B$ of bcc Fe,¹¹ suggesting electron transfer from the metalloid atoms to the d band of the Fe atoms.

The reduced hyperfine field $H_{\text{hf}}(T)/H_{\text{hf}}(0)$ or equivalently the reduced magnetization $M(T)/M(0)$ of the amorphous phase decreases more rapidly with reduced temperature T/T_C rather than those of crystalline ferromagnets as shown in Fig. 6. This kind of rapid decrease can be explained in terms of either a distribution of exchange interactions in the amorphous phase or high metalloid contents.

Resonant microwave cavity response of amorphous ribbons

A. N. Medina, M. Knobel, S. Salem-Sugui, and F. G. Gandra

Universidade Estadual de Campinas, Instituto de Física, Cidade Universitária, Campinas, SP, 13083-970, Brazil

In this study we report microwave experiments on the amorphous ribbon $\text{Fe}_{4.6}\text{Co}_{70.4}\text{Si}_{15}\text{B}_{10}$ using the usual setup for magnetic resonance experiments at 9.4 GHz to observe the cavity response. Several samples cut from the same tape were annealed, either in the presence or in the absence of a magnetic field. For each sample the magnetization and magnetoimpedance (MI) curves were obtained, with MI ratios between 1% and 40%. The magnetic resonance spectrum consists of the usual ferromagnetic line and an anomalous low field cavity response for $H < 100$ Oe. The shape of this low field signal depends on the thermal treatment and on the orientation of the external field. We believe that this signal is in part a ferromagnetic peak but it also carries information of the skin-depth changes with a sweeping magnetic field. © 1996 American Institute of Physics. I. INTRODUCTION

Since the discovery of amorphous metals, their magnetic properties have been extensively studied due to their enormous potential in technological applications. In recent years these investigations have taken a strong impulse with the development of nanocrystalline materials,¹ and more recently, with the observation of the so-called giant magnetoimpedance (GMI) effect.²⁻⁴ GMI consists of large (up to 360%)⁵ and sensitive (up to 1700%/Oe)⁶ variations in the impedance (Z) of soft magnetic wires or ribbons upon the application of an external magnetic field (H). The field and frequency response of the impedance reflects, in a complex way, the behavior of the magnetic permeability, and can be roughly modeled using the classical Maxwell equations of electrodynamics. There are, however, several points that remain unclear, such as the effect of induced anisotropies and the contribution of the different magnetization processes to the whole phenomenon. In particular, samples submitted to peculiar thermal treatments^{6,7} or tensile stresses display clear maxima in the $Z(H)$ curves, generally located at the materials' effective anisotropy field H_k .

In the present work, we study the GMI effect for a nearly zero magnetostriction amorphous ribbon subjected to different thermal treatments. The induced anisotropies are analyzed by ferromagnetic resonance (FMR) measurements, which also allows one to obtain valuable information about the overall magnetization process. We observed an interesting peak in the low-field side of the derivative resonance spectra that is similar to the one recently observed in amorphous thin films by Rivoire and Suran.⁸ According to these authors, this peak is directly related to the magnetization process that occurs along the hard axis, in the case of films with in-plane uniaxial anisotropy. Besides the fact that our samples are amorphous ribbons (thickness 22 μm), a major difference in the spectra is that the observed peak displays some differences in shape. These differences depend on the thermal treatment and magnetic field orientation and we believe that they can be related to the same mechanism that is responsible for the MI effect.

II. EXPERIMENTAL PROCEDURES AND RESULTS

An amorphous ribbon of nominal composition $\text{Co}_{70.4}\text{Fe}_{4.6}\text{Si}_{15}\text{B}_{10}$, 4 mm width and 22 μm thick, was produced by melt-spinning in air. This sample is characterized by a slightly negative magnetostriction constant ($\lambda_s = -1 \times 10^{-7}$), which is responsible for its very soft magnetic behavior. Four adjacent sections 1.5 cm long of the same amorphous ribbon were subjected to different magnetic annealing conditions. Sample a was kept in the as-quenched state while the remaining samples were annealed at 250 °C for 15 min in argon. Sample b was heated and cooled in zero field (ZFT) while for samples c and d an external field of 2 kOe was applied transversely or longitudinally to the ribbon axis. The field was maintained until the sample was cooled to room temperature.

The field dependence of the impedance in the 1.5-cm-long ribbons was measured at a fixed frequency (100 kHz) using a vector lock-in amplifier with a driving current intensity of 20 mA parallel to the ribbon axis and with dc applied fields up to 30 Oe generated by a Helmholtz coil. The contacts were made with silver paint and have typically 1 Ω resistance. Figure 1 shows the MI ratio, defined as $[Z(H) - Z(H=0)]/Z(H=0)$, obtained for H parallel to the ribbon axis for all samples. For H perpendicular to both of them, the ribbon axis and current direction—as well as for dc driving currents—the MI ratio was always less than the experimental error. The curves obtained for samples a and d show a similar MI behavior while for the ZFT sample less than 1% MI ratio was observed. This suggests that, in our case, even after annealing with a longitudinal field, there is a remaining contribution to the transverse permeability. On the other hand, ZFT promoted a strong internal stress relief, drastically reducing the magnetoelastic anisotropy and the MI ratio, in agreement with recent data.⁷ A rather strong peak close to 40% is observed for sample c, which is also in good agreement with previous measurements.^{2,7}

The microwave experiments were carried out at room temperature in a conventional X band magnetic resonance spectrometer using a commercial Varian TE₁₀₂ cavity with 100 kHz modulation field and 0.2 mW power. The sample was positioned at the center of the cavity such that the ex-

FIG. 1. Magnetoimpedance ratio for the different magnetic annealing conditions as described in the text. The magnetic field was applied parallel to the direction of the ac electrical current.

ternal magnetic field was in plane with the sample and directed either along or transverse to the ribbon axis. For these measurements, 2×2 mm samples were cut from the annealed ribbons. Since the dimensions of these samples are very different from those of MI measurements, a different demagnetization factor must be considered. In this setup the magnetic field can sweep from positive to negative values continuously.

Figure 2 shows the resonance spectrum obtained for sample c where one can clearly see the normal FMR mode

FIG. 2. Magnetic resonance spectrum for sample c obtained with external field along the ribbon axis. A peak below 100 Oe and the normal mode of the FMR at 1.25 kOe are clearly observed.

FIG. 3. Magnetic resonance spectra and normalized magnetization for the external field oriented along the ribbon axis.

and a low field peak. Low field structures have been observed for a long time in FMR studies in metals.^{9,10} Recently Rivoire and Suran⁸ described experimental results in amorphous thin films, which are very similar to our results. They calculated the resonance spectra for an amorphous thin film with uniaxial in-plane anisotropy, considering the movement of magnetization for H oriented along the hard axis. For this configuration two resonance modes can be calculated, for $H < H_k$ and $H > H_k$, respectively. For such low anisotropy materials, the solution for $H < H_k$ requires that the working frequency be smaller than the natural frequency, which we estimated to be close to $\nu_0 = 1$ GHz in our case. If $\nu > \nu_0$, they show that the low field peak can be described by a complicated function centered at H_k . This peak is obtained for H along the hard axis and the rf microwave field along the easy axis.

Figures 3 and 4 show the low field part of the resonance spectra (absorption derivative) together with the normalized magnetization for each orientation of the external field relative to the ribbon. The spectra for the ZFT sample are essentially the same for both field orientations owing to the negligible magnetic anisotropy. However, there are significant differences in the magnetic resonance spectra for the remaining samples, which depend on the induced anisotropy. For these samples the spectra are quite different for each field orientation and a second peak (hereafter called P2) is clearly visible superposed on the expected one. Assuming that the usual FMR theory explains the main low field peak,⁸ it is interesting to check if peak P2 can be associated with the same mechanism that drives the MI effect, that is, field induced changes in the sample's magnetic penetration depth. In

FIG. 4. Magnetic resonance spectra and normalized magnetization for the external field oriented transversely to the ribbon axis.

the same way as the microwave power was absorbed in the FMR, these impedance changes would induce a slight decoupling of the microwave cavity that would be detected by the reflected microwave power.

For sample d the FMR peak [Fig. 3(a)] is practically absent for H parallel to the easy axis (which is now along the ribbon axis), but is quite large when H is along the hard axis [Fig. 4(d)]. Since the MI is very low for H parallel to the ribbon's axis and negligible for H transverse to the ribbon, we can infer that the peak observed in Fig. 4(d) corresponds basically to the expected FMR signal, which is strongly reduced when the field is applied along the easy axis [Fig. 3(d)].

The resonance results indicate that there is a net orientation of the domains along the ribbon axis already in the as-quenched ribbon (sample a), which is probably a consequence of the quenching process. In Fig. 4(a) it is possible to see the FMR peak and peak P2 centered at 50 Oe. For H parallel to the easy axis [Fig. 3(a)] only the contribution to peak P2 is left.

The resonance spectra for samples c and a are very similar, if one considers the different anisotropy. Sample c was treated with H transverse to the ribbon and therefore, the hard and easy axis directions are inverted relative to samples a and d. Although the 40% MI ratio was observed in sample c, the resonance peak P2 observed for the longitudinal field [Fig. 3(c)] was of the same magnitude of the FMR peak.

P2 is displaced toward larger H values in comparison to the peak observed in the GMI. Notice, however, that the reduced dimension of the sample increases the demagnetization field. Also, additional stresses introduced when the sample was cut from the ribbon can induce non-negligible anisotropies.

In conclusion, we have found that the MI effect is strongly dependent on the magnetic anisotropies induced by the different thermal treatments. In order to obtain large MI ratios, it is important to have not only large permeabilities, but also tailored anisotropies. It was also shown that FMR is a suitable technique to study the anisotropies in these ribbons. Two superposed peaks were observed in the low field part of the magnetic resonance spectrum for H along the hard axis. One peak is explained by the FMR theory and the second peak is possibly associated with the same skin-depth effect that promotes the observed MI. However, FMR experiments and calculations must be extended for H parallel to the easy axis and rf along the hard axis in order to obtain detailed information from peak P2. Also, further investigations on the normal FMR mode can provide important information about the anisotropy field.

We report on the evolution, with the thermal treatment parameters, of the remanence and coercive force of amorphous melt spun ribbons having compositions of $\text{Fe}_{77.5}\text{Si}_{13.5}\text{B}_9$, $\text{Fe}_{76.5}\text{Cu}_1\text{Si}_{13.5}\text{B}_9$, and $\text{Fe}_{74.5}\text{Ta}_3\text{Si}_{13.5}\text{B}_9$. The thermal treatments were carried out by using the current annealing technique with and without the simultaneous application of a tensile stress along the axis of the samples. Our results show that upon low temperature (low current), short time treatments both the remanence and the coercive force are basically determined by the characteristics of the effective anisotropy induced during the treatment. In contrast, high temperature (high current) treatments result in values of both quantities that are linked to the (partial or total) accomplishment of the first stage of the crystallization process of the samples. © 1996 American Institute of Physics.

[S0021-8979(96)31008-7]

I. INTRODUCTION

The elevated atomic mobility characteristic of the amorphous state allows, through appropriate thermal treatments, control of both the effective magnetic anisotropy and the hysteresis in melt spun transition metal-metalloid amorphous alloys.¹ That elevated mobility is a direct consequence of the metastable nature of the amorphous phases which upon suitable anneals decay in one or more stages toward stable distributions of crystalline phases. As was shown by Yoshizawa *et al.*² the crystallization process can also result in very interesting soft magnetic properties. The crystallization-induced softening of some Fe-based amorphous materials³ is linked to the appearance, of a nanostructure characterized by grain sizes of the order of 10 nm which are strongly coupled to an amorphous matrix in which they are embedded. That coupling allows the average down to small values of the interactions of the magnetic moments with their randomly oriented local easy axes³ and the consequential observation of high permeabilities and small coercive forces (a reduced effective magnetostriction resulting from the two-phase nature of the samples is also observed in the prototypical FeCuNbSiB system). Since it must be adequately scaled to the effective exchange correlation length the critical microstructural parameter to be controlled during the crystallization process is the grain size. There are two basic strategies to achieve that control: to take advantage of the kinetics of the crystallization process⁴ and to use adequate additives to limit the grain growth and or enhance the occurrence of nucleation.⁵

The authors have recently presented results⁶ about the induction of magnetic anisotropy in different FeSiB-based amorphous systems characterized by the partial substitution of Fe by Cu and Ta. In the present work we will report on the

evolution, after different thermal treatments, of the hysteretic parameters of the samples of those systems.

II. PREPARATION OF SAMPLES AND EXPERIMENTAL TECHNIQUES USED

Ribbon-shaped samples of nominal compositions $\text{Fe}_{77.5}\text{Si}_{13.5}\text{B}_9$ (FeSiB), $\text{Fe}_{76.5}\text{Cu}_1\text{Si}_{13.5}\text{B}_9$ (FeCuSiB), and $\text{Fe}_{74.5}\text{Ta}_3\text{Si}_{13.5}\text{B}_9$ (FeTaSiB) and having a width of 4 mm and an average thickness of 20 μm were prepared by means of a single roller melt spinning device. The annealing treatments were performed by using the so-called current annealing technique. Such current anneals were carried out with and without the simultaneous application of a longitudinal tensile stress in the range from 150 to 200 MPa (applied stress and stress free anneals, respectively).

The phase distribution of both the as-quenched and thermally treated samples was examined by means of x-ray diffraction. The hysteretic measurements (obtained in 10-cm-long samples) were performed by means of a computer controlled dc (2–10 Hz) induction setup described in Ref. 7. Both the remanence and coercive force of the samples were evaluated from the loops measured under a maximum applied magnetic field of 2000 A/m.

III. RESULTS AND DISCUSSION

According to the x-ray diffractograms taken in the as-quenched ribbons these samples were amorphous down to the resolution of the technique. In Fig. 1(a) we present the results obtained in the FeSiB samples for the evolution with the annealing time, t_{ann} , of the remanence, M_r . We must note that after all the treatments the maximum applied field was clearly sufficient to achieve technical saturation of the samples and that there were no indications concerning the shape of the measured hysteresis loops after the occurrence

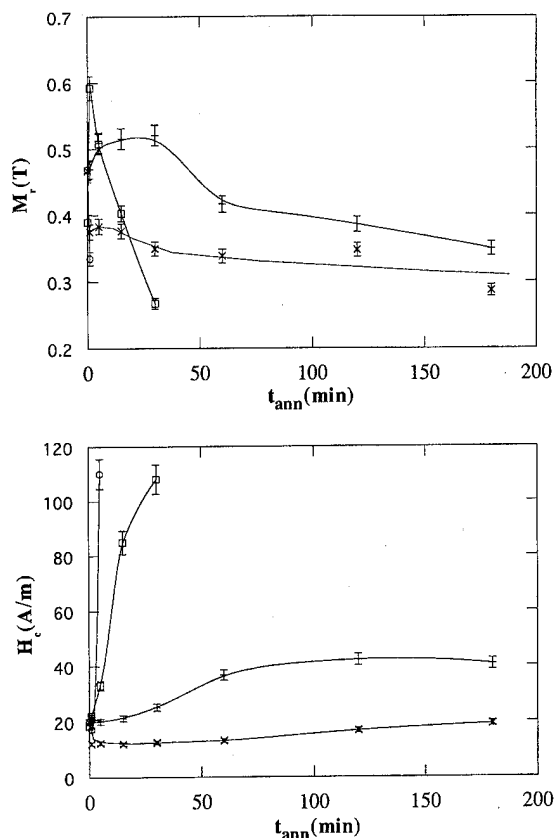

FIG. 1. (a) Annealing time dependence of the remanence measured in samples of the FeSiB system: (+) 2.1 A; (\times) 2.1 A and 200 MPa; (\square) 2.35 A and (\circ) 2.35 A and 200 MPa. (b) Annealing time dependence of the coercive force measured in samples of the FeSiB system: (+) 2.1 A; (\times) 2.1 A and 200 MPa; (\square) 2.35 A; and (\circ) 2.35 A and 200 MPa.

of phase separation. In the particular case of the samples treated with a current of 2.1 A, the stress free anneals were associated with an initial increase of M_r with t_{ann} . That increase led to a maximum being achieved after 25 min. For longer treatment times a steady decrease of M_r was observed. In the case of the applied stress annealed sample treated by using the same current, the measured evolution of M_r with t_{ann} was characterized by a rapid decrease of the remanence with an increase of the treatment time, down to a more or less annealing time-independent value. A clearly different behavior was observed in the sample treated using higher currents: For annealing times longer than a few minutes the remanence measured in both the applied stress and stress free annealed samples decreased markedly. Results corresponding to the variation with t_{ann} of the coercive force, H_c , measured in the FeSiB samples are shown in Fig. 1(b). Clear corresponding with the remanence results, a remarkable difference was observed between the samples treated at low and high current intensities: Whereas in the case of the samples treated at 1.8 A the coercive force was weakly dependent on the treatment time, it increased rapidly with t_{ann} in the samples treated at 2.1 A. It is interesting to remark that short time stress free anneals allowed us to obtain a coercive force of the order of 12 A/m, that is, 55% of the measured (22 A/m) as-quenched value.

According to the results reported in Ref. 6, low intensity treatments carried out in samples of the FeSiB system (both with and without applied stress) resulted in a tendency to shift the effective easy axis of the samples toward the direction transverse to the ribbon axis. This result can clearly account for the origin of the observed behavior of both the M_r vs t_{ann} and H_c vs t_{ann} low current curves. Regarding the occurrence of a maximum in the stress free anneals of 2.1 A curves, we suggest that it could be linked to inhomogeneities in the anisotropy distribution resulting either from the partial elimination of the as-quenched anisotropies (of magnetoelastic origin and therefore linked to the stresses built-in during the quenching process) or from the occurrence of temperature gradients across the ribbon thickness associated with the use of the current annealing technique. The rapidly growing transverse anisotropy measured⁶ in the case of the high current treatments underlies the annealing behavior of the hysteretic parameters of these samples and, according to the corresponding x-ray diffractograms, is linked to the onset of the first stage (FeSi precipitation) of the crystallization process.

Figure 2(a) shows data corresponding to the treatment time evolution of the remanence measured in the FeCuSiB annealed samples. From Fig. 2(a) it is possible to conclude that M_r is only slightly changed by the stress free characteristic of the applied stress anneals if they are carried out by using low current intensity. In contrast, if the treatments are carried out by applying higher currents during long annealing times they result in a remarkable increase of the reduced remanence values.

A similar dependence on t_{ann} was observed for the H_c values measured in the FeCuSiB annealed samples: They were not remarkably changed by the low current treatments and increased steadily with treatment time in the case of higher current treatments.

Again the results obtained in this system for the annealing evolution of the induced anisotropy⁶ seem to explain the evolution of the remanence and coercivity: The induced easy axis was, for the low current treatments, parallel to the ribbon axis and its intensity was independent of the treatment time for t_{ann} longer than a few minutes. As in the FeSiB system the samples treated using the high current intensity value were partly crystallized (an average grain size of 100 nm was estimated from x-ray diffraction results).

Data corresponding to the annealing time dependence of both the remanence and coercive force measured in FeTaSiB are presented in Figs. 3(a) and 3(b), respectively. Different from the previous systems, for short treatment times the remanence increased in a similar way after low and high current stress free anneals. After this initial increase maxima taking place at $t_{ann}=20$ min (stress free annealed samples) and at 60 min (applied stress annealed samples) were observed (a further increase of the remanence with that of the treatment time was measured in the case of the low annealing current samples). The evolution of the remanence corresponding to the applied stress treatments was qualitatively similar to that observed in the stress free ones with the only remarkable difference of the observation being the less pronounced maxima. Regarding the coercive force results, the

FIG. 2. (a) Annealing time dependence of the remanence measured in samples of the FeCuSiB system: (+) 1.8 A; (○) 1.8 A and 150 MPa; and (□) 2.2 A. (b) Annealing time dependence of the coercive force measured in samples of the FeCuSiB system: (+) 1.8 A; (○) 1.8 A and 150 MPa; and (□) 2.2 A.

stress free and applied stress anneals led to a very different evolution: whereas the treatments carried out under applied stress produced a slight increase of the coercivity, in the case of the stress free treatments a noticeable softening of the material (down to H_c values of the order of 4 A/m comparable to the best values obtained in the FeCuNbSiB system) was detected after anneals carried out during times in the range from 5 to 30 min. As for the high current anneals, it was possible to show how, after originating a decrease of H_c for short treatment times, they resulted, both for the stress free and the applied stress cases, in a clear tendency to increase of coercivity. We must remark that, in the particular case of the applied stress samples treated for times longer than 60 min and using 2.0 A, the hysteresis loop clearly evidenced the occurrence in the samples of two weakly coupled magnetic phases (and therefore the partial accomplishment of crystallization).

From the correlation of these results with those corresponding to the induced anisotropy⁶ and phase distribution of the FeTaSiB annealed samples, it is possible to conclude that the maxima observed in the M_r vs t_{ann} curves corresponding to the samples treated using a current of 2.0 A were related to the onset of crystallization (this onset was also related to the increase of the remanence observed in the low current long

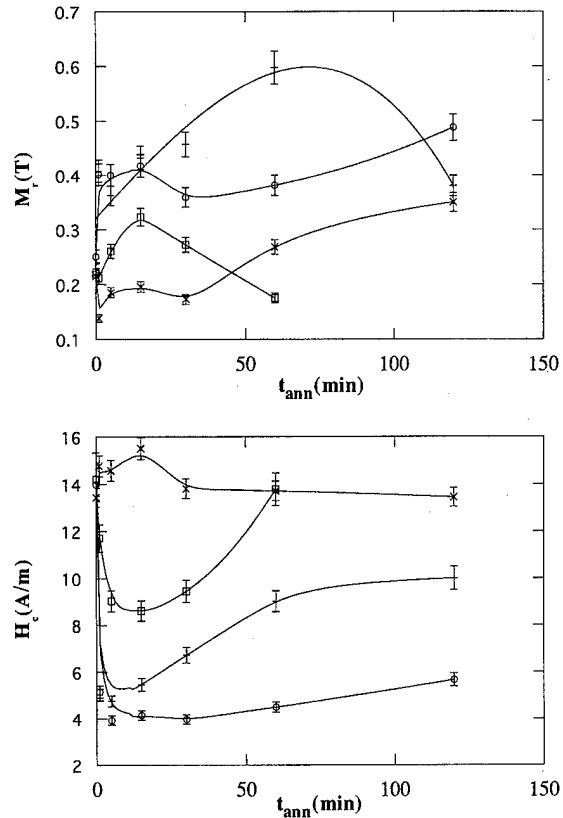

FIG. 3. (a) Annealing time dependence of the remanence measured in samples of the FeTaSiB system: (○) 1.8 A; (×) 1.8 A and 200 MPa; (+) 2.0 A, and (□) 2.2 A and 200 MPa. (b) Annealing time dependence of the coercive force measured in samples of the FeTaSiB system: (○) 1.8 A; (×) 1.8 A and 200 MPa; (+) 2.0 A, and (□) 2.2 A and 200 MPa.

treatment time anneals). Again from the induced anisotropy results, the increase of the remanence observed in the stress free, low current short time anneals should be ascribed to the induction of a large longitudinal anisotropy. Finally, let us point out that the very different evolution with t_{ann} of the coercive force of the low current stress free and applied stress annealed samples was not correlated to that of the anisotropy resulting from the treatments since both types led to the induction of a longitudinal anisotropy of a similar value. We then conjecture about the presence in the applied stress annealed sample of a larger amount of anisotropy inhomogeneities, which could be linked either to the partial elimination of the as-quenched anisotropies or to the induction during the current anneal of an inhomogeneous anisotropy.

Results of a pulsed NMR study of the soft ferromagnetic amorphous alloy $\text{Co}_{74.26}\text{Fe}_{4.74}\text{Si}_{2.1}\text{B}_{18.9}$ in the as-cast and the heat treated (at 410 °C for 12 minutes) states re reported. The measurements were performed at 4.2 K. Very intense resonances lines are observed in the frequency region 10–110 MHz (range of the present study), for both as-cast and heat treated samples. The NMR signal intensity depends on the rf power level; this suggests the existence of several magnetic regions with different local anisotropies. We identify NMR lines in two frequency ranges: (a) 10–50 MHz, which probably come from ^{57}Fe , ^{11}B , and ^{29}Si nuclei in Fe–Si-like regions and ^{57}Fe in Co(Fe) solid solutions; and (b) for frequencies above 50 MHz, lines from ^{59}Co (and probably ^{11}B) in Co-rich crystalline-like environments with short-range order as in Co_2B , in the range 70–110 MHz. In the higher frequency region, the NMR spectra suggest that the environments are similar to Co_3B and to Co(B) solid solutions. For the heat treated sample, lines above 95 MHz disappear for lower rf power levels; also, this sample shows lines around 75 MHz narrower than those for the amorphous alloy. These results give evidence of the concentration inhomogeneity of the samples, both in the as-cast and heat-treated forms. © 1996 American Institute of Physics. [S0021-8979(96)64908-0]

Evolution from soft to hard magnetic behavior in Co-based devitrified glassy alloy

G. Bottoni, D. Candolfo, and A. Cecchetti

INFM—Dipartimento di Fisica, Università di Ferrara, 44100 Ferrara, Italy

From the amorphous alloy 6030V having the composition $\text{Co}_{71.5}\text{Fe}_{1.5}\text{Mo}_1\text{Mn}_4\text{Si}_{13}\text{B}_9$, a series of devitrified specimens with increasingly coarser microstructure and magnetic hardening is produced by annealing. From the features of the coercivity, the squareness ratio, the rotational hysteresis integral, and the magnetic interactions we infer that the magnetic hardening is due initially ($T_a < 600^\circ\text{C}$) to a strengthening of the pinning effect of the precipitates on the domain walls, and then ($T_a > 600^\circ\text{C}$) to the formation of single-domain Co crystallites where the magnetization reversal mode is of incoherent type. © 1996 American Institute of Physics. [S0021-8979(96)31108-3]

I. INTRODUCTION

The devitrification process in glassy alloys may produce a magnetic softening or a magnetic hardening of the material, depending on the microstructure formed during the annealing treatment. In the commercial amorphous alloy 6030 Vitrovac (Vacuumschmelze-D) of nominal composition $\text{Co}_{71.5}\text{Fe}_{1.5}\text{Mo}_1\text{Mn}_4\text{Si}_{13}\text{B}_9$, the thermal treatment, performed in the temperature range of $500\text{--}750^\circ\text{C}$, gives rise to a magnetic hardening which depends on the annealing temperature T_a .

The purpose of this work is to analyze the magnetization process occurring at various stages of the magnetic hardening as deducible from the feature of some magnetic properties, i.e., the coercivity H_c , the squareness ratio M_r/M_s , the rotational hysteresis integral R , and the magnetic interactions among the crystallites.

II. EXPERIMENTAL RESULTS AND DISCUSSION

A. Influence of the annealing treatments on the magnetic properties

In the amorphous state (or the as-received state: ar.) the 6030V alloy is furnished in the form of a ribbon, $23\text{ }\mu\text{m}$ thick, having the following physical properties: saturation magnetization $M_s = 652\text{ emu/cm}^3$, coercivity $H_c = 0.01\text{ Oe}$, Curie temperature $T_C = 365^\circ\text{C}$, crystallization temperature $T_{cr} = 480^\circ\text{C}$. Disk specimens, 3 mm in diameter [suitable for magnetic measurements by a vibrating sample magnetometer (VSM)], cut from the ribbon, are annealed in vacuum at various temperatures ($500\text{--}750^\circ\text{C}$) and times so as to obtain a set of samples with increasing granularity (Fig. 1) and coercivity (Fig. 2). This treatment gives rise to an increase of coercivity up to 400 Oe (Fig. 2), while M_s decreases with T_a and tends to a limit value of 600 emu/cm^3 .

The crystalline phase is principally constituted of fcc crystallites having a Curie temperature of 750°C which is lower than that of the pure Co due to the formation of compounds or impurities in the Co lattice.¹

The behavior of the squareness ratio against the annealing temperature T_a (Fig. 2) is a useful parameter for understanding the magnetization processes in the various stages of magnetic hardening. In the ar. state $M_r/M_s \cong 1$ in a core wound ribbon, but it decreases to 0.025 in the disk samples

due to the demagnetizing effect. Owing to the magnetic hardening, M_r/M_s increases in the disk samples against the demagnetizing field and reaches a peak value of 0.7 (Fig. 2), then it tends to a limit value of 0.5 which corresponds to the value of the squareness ratio of an assembly of randomly oriented particles.

Noting that in the amorphous state the dominant magnetization process is the domain wall (dw) motion, the initial increase of M_r/M_s and H_c , when the crystallite formation starts, is ascribed to a strengthening of the pinning effect that the small crystallites, dispersed in the amorphous matrix, exert on the dw.² No evidence for attributing the magnetic hardening to exchange coupling between precipitates and the soft magnetic phase³ was found in the present system. There-

FIG. 1. Transmission electron microscopy micrographs of the devitrified samples after annealing for 1 h at $T_a = 550^\circ\text{C}$ (a), 650°C (b), and 750°C (c).

FIG. 2. The coercivity and the squareness ratio vs annealing temperature.

fore, we assume that the increase of the pinning strength on the dw, due to the formation of precipitates, is the main cause of the initial magnetic hardening of the material. This assumption is supported by the evolution of the rotational hysteresis integral R which indicates that at this stage the dominant magnetization process is still the dw motion (Table I). We remember that R is a number defined by $R = \int W_r / M_s d(1/H)$, where W_r is the rotational loss, and the values of R depend on the magnetization reversal mechanism.⁴ For the ar. sample $R \approx 0$ because the rotational hysteresis losses are very small; but, as the magnetic hardening increases, R goes up to about 3.5, which approaches the typical value for the magnetization reversal model by dw motion.⁵ High values of R are also typical of the curling model in elongated single-domain particles⁴ or of the fanning model for particles behaving as chains of spheres touching each other by a surface area.^{6,7} However, these latter models do not fit the current case since they involve the presence of elongated particles, while at this stage the sample is still composed of an amorphous phase containing crystallites of irregular shape (Fig. 1).

As the devitrification proceeds for higher annealing temperatures, the coercivity increases, while the rotational hysteresis integral decreases and tends to values between 1.5 and 1, and the squareness ratio converges to 0.5 (Fig. 2). These values coincide with those of the incoherent reversal model for an assembly of randomly oriented single-domain particles.⁴

The successive decrease of H_c for $T_a > 700^\circ\text{C}$ (Fig. 2), when the sample is fully crystallized and the material is rather brittle, is ascribed to the formation of dw in the biggest crystallites.

FIG. 3. Rotational hysteresis loss vs amplitude H of the rotating field, measured at two different temperatures, for the sample annealed for 1 h at 530°C and the sample annealed for 1 h at 650°C .

B. Magnetic measurements at various temperatures

It is interesting to note the magnetic behavior of the partially devitrified samples at temperatures higher than the Curie temperature of the amorphous phase, i.e., $T > 365^\circ\text{C}$. In this paper we report the data obtained on two samples: the former sample is one where the dominant magnetization process at room temperature is still the dw motion (the sample annealed for 1 h at 530°C), the latter is a sample where the dominant magnetization process is the incoherent reversal mode, similar to the systems of single-domain particles (the sample for annealed 1 h at 650°C).

Table I shows some magnetic parameters detected on these samples at room temperature (22°C) and at $T = 382^\circ\text{C}$. The squareness ratio of the sample annealed at 530°C , which is 0.7 at $T = 22^\circ\text{C}$, drops to 0.28 at $T = 382^\circ\text{C}$ while the coercivity increases. This is due to the disappearance of the soft ferromagnetic amorphous phase whose amount is about 60% as deducible by comparing M_r/M_s at room temperature and at $T = 382^\circ\text{C}$. For the sample annealed at 650°C , where the fraction of the soft phase is about 25%, the variation of M_r/M_s is smaller than in the previous case and H_c does not increase at $T = 382^\circ\text{C}$ (Table I).

Figure 3 shows the rotational hysteresis loss W_r vs amplitude H of the rotating field for the two samples of Table I measured at two different temperatures. The losses are larger at $T = 22^\circ\text{C}$ owing to the greater values of anisotropy at room temperature. At this temperature, the rotational hysteresis integral R is 2.95 for the sample containing the highest fraction of amorphous phase where the reversal magnetization is principally governed by the dw motion, while R becomes equal to 1.36 for the sample containing the lowest

TABLE I. Magnetic parameters monitored at two different temperatures on two samples annealed for 1 h at different T_a .

Sample annealed at $T_a = 530^\circ\text{C}$				Sample annealed at $T_a = 650^\circ\text{C}$		
$T (^\circ\text{C})$	M_r/M_s	H_c (Oe)	R	M_r/M_s	H_c (Oe)	R
22	0.68	129	2.95	0.60	390	1.36
382	0.28	145	1.56	0.45	265	1.21

FIG. 4. Deviation ΔM from the noninteracting particle equation for the sample annealed for 1 h at 530 °C. The measurements are made at three different temperatures.

FIG. 5. Deviation ΔM from the noninteracting particle equation for the sample annealed for 1 h at 650 °C. The measurements are made at three different temperatures.

fraction of the amorphous phase which behaves similarly to a system of single-domain particles following a fanning reversal model. For $T=382$ °C a more drastic reduction of W_r occurs in the former sample because of the disappearance of the amorphous phase, and R drops to 1.56 because only the crystallites present in the specimen remain magnetically effective. This value of R is close to that of the sample annealed at 650 °C containing the highest fraction of crystallites and where the dominant magnetization mechanism is the incoherent reversal mode.

C. Magnetic interactions

In the fine particle systems the magnetic interactions are of interest because of applications in the field of magnetic recording. These interactions are often studied by the method of the two remanence curves.⁸ According to this method the particle interactions are evaluated by the deviation ΔM from the Wohlfarth equation valid for a system of noninteracting particles: $\Delta M = M_d(H) - [1 - 2M_r(H)]$ where $M_d(H)$ and $M_r(H)$ are the demagnetizing and remagnetizing remanence curves in reduced units.⁸

Figures 4 and 5 show these curves measured (using a VSM) at three different temperatures ($T=-196$ °C, $T=22$ °C, and $T=382$ °C) for the two samples annealed at 530 and 650 °C. The strongest interactions are present in the sample annealed at 650 °C which contains the highest fraction of crystalline phase. No large difference occurs between the curves at $T=-196$ °C and $T=22$ °C for this sample. This indicates that the fraction of superparamagnetic crystallites at room temperature is low, the particle interactions possibly preventing the superparamagnetic relaxation. We note that an evaluation of the overall effect of the interactions may also be deduced from the area between the curve ΔM and the axis $\Delta M=0$ of the plot of Fig. 5, i.e., the so-called Δ plot area.⁹ A large reduction of the interactions is observed at $T=382$ °C, which is ascribed to various effects: a decrease of

the magnetic moment of the crystallites, an increase of the fraction of superparamagnetic particles, and the disappearance of the amorphous phase which may favor the flux conduction. In the sample annealed at 530 °C, which contains the lowest fraction of crystals dispersed in the amorphous matrix, the interactions are weaker than in the previous case and the difference between the curve at $T=22$ °C and $T=-196$ °C is more pronounced indicating the presence of a higher fraction of superparamagnetic crystallites at room temperature. Particularly, the positive ΔM deviation which appears in correspondence with $M_d(H)/M_r(\infty)=0.7$ at room temperature, is ascribed to a resistance to remagnetization.⁸ At $T=382$ °C the interactions practically disappear (ΔM fluctuates around zero: Fig. 4) since in this sample the crystallites are well diluted in a nonferromagnetic matrix.

As a conclusion, we have shown that the thermal treatments of the present amorphous alloy give rise to a system of magnetic particles (or crystallites) which, unlike the particulate media, are embedded in a magnetic matrix. Consequently, the magnetic behavior of this system (i.e., occurrence of domain wall motion, magnetization reversal model, interactions between crystallites, etc.) may be controlled by regulating, through suitable thermal treatments, both the fraction of the magnetic matrix and the crystallite size.

Nanocrystalline Fe-M-B-Cu (M=Zr, Nb) alloys with improved soft magnetic properties (abstract)

A. Makino and T. Bitoh

Central Research Laboratory, Alps Electric Co. Ltd, Nagaoka 940, Japan

A. Inoue and T. Masumoto

Institute for Materials Research, Tohoku University, Sendai 980, Japan

We have recently succeeded in producing good soft magnetic properties and high saturation magnetic density (B_s) for nanocrystalline Fe-M-B (M=Zr, Hf, or Nb) ternary alloys prepared by melt spun¹ and sputtered technic.² The alloys have the mixed structure consisting of α -Fe particles with 10–20 nm in size embedded in a remaining amorphous phase. The nanocrystalline bcc Fe₉₀Zr₇B₃, Fe₈₉Hf₇B₄ and Fe₈₄Nb₇B₉ alloy ribbons subjected to the optimum annealing exhibit high B_s of 1.5–1.7 T as well as high effective permeability (μ_e) of 22 000–32 000 at 1 kHz.³ The soft magnetic properties of the nanocrystalline Fe-M-B alloys were found to be improved by adding small amounts of Cu and by optimizing the chemical composition. The addition of Cu to the alloys decreases the bcc grain size. The excellent soft magnetic properties (high μ_e of 100 000 at 1 kHz combined with high B_s of 1.53 T) can be achieved in the region where small grain size as well as nearly zero magnetostriction are obtained, which is attained in the compositional range around Fe₈₄Nb_{3.5}Zr_{3.5}B₈Cu₁. The soft magnetic properties can be further improved by preannealing before crystallization treatment, probably resulting from the decrease in the distribution of the grain size at the crystallized state. Consequently, the μ_e reaches the maximum value of 120 000 for the nanocrystalline Fe₈₄Nb_{3.5}Zr_{3.5}B₈Cu₁ alloy. © 1996 American Institute of Physics.

Comparison of experimental and theoretical initial permeability taking into account anisotropy dispersion in CoNbZr thin films (abstract)

M. C. Contreras, M. Rivas, J. F. Calleja, and I. Iglesias

Departamento de Física, Universidad de Oviedo, Spain

M. Guyot, V. Cagan, and R. Krishnan

Laboratoire de Magnétisme et d'Optique de Versailles, C.N.R.S., France

For thin films with very well defined uniaxial anisotropy, initial permeability spectra in the hard direction may be well described by Landau–Lifshitz theory that, in the low frequency range, is reduced to $\mu_i = 4\pi M_s/H_k$. But the switching process of the magnetization becomes more complex when it is dominated by local variations of the anisotropy, what is known as magnetization ripple. Then, initial permeability at low frequency may be expressed as $\mu_i = 4\pi M_s/H_{\text{eff}}$. Here, effective field H_{eff} is, from ripple theory: $H_{\text{eff}} = H_k(1 + b + c)$, the terms b and c being additional anisotropy fields due to short and long range magnetization fluctuations. Measurements of H_k , b , and c can be obtained from the transverse bias permeability that has been measured along easy and hard axis by transverse Kerr effect. We obtain values of $b + c$ between 0.04 and 0.30, what imply a reduction of permeability between 4% and 30% due to the dispersion of the anisotropy. Saturation magnetization was measured using a VSM and also with a computer aided hysteresismeter. Then, initial permeability was measured along hard axis using an inductive system previously described. © 1996 American Institute of Physics. [S0021-8979(96)65008-6]

Crystallization behavior of a mechanically alloyed amorphous $\text{Fe}_{80}\text{Zr}_8\text{B}_{11}\text{Cu}_1$ alloy

Department of Physics, Nanjing University, Nanjing 210008, People's Republic of China

An amorphous alloy of $\text{Fe}_{80}\text{Zr}_8\text{B}_{11}\text{Cu}_1$ has been prepared by mechanical alloying, milled for 72 h, and annealed in the temperature range from 673 to 1173 K. The crystallization behavior of this sample at different annealing temperatures has been investigated by x-ray diffractometry, electron microscopy, and Mössbauer spectroscopy. With the increase of annealing temperature, about a 15 nm bcc phase is formed in the amorphous base. Upon further increasing the annealing temperature to 1173 K, in addition to the metastable α -Fe (Zr,B) phase, a ZrB_2 phase appears. Furthermore, the results from Mössbauer spectroscopy reveal that there are two different magnetic areas in these amorphous phases at different annealing temperatures. © 1996 American Institute of Physics. [S0021-8979(96)31208-X]

I. INTRODUCTION

Recently, excellent soft magnetic properties and high saturation magnetization B_s have been confirmed for some nanocrystalline alloys in the FeCuNbSiB ,^{1,2} Fe-M-B ($\text{M} = \text{Zr, Hf, or Nb}$),³ and Fe-P-C-Ge-Cu systems,⁴ etc. Of these alloys, the highest B_s with good soft magnetic properties has been achieved for the Fe-M-B ternary alloys, because an amorphous phase with Fe concentrations higher than those in the other systems is obtained owing to the high glass-forming ability of M elements and the formation of a nanocrystalline bcc phase.

Usually, Fe-M-B nanocrystalline alloys are prepared by annealing melt-spun amorphous ribbons at a temperature above the crystallization temperature. But in some cases such as magnetic cores used in inductors or irregular shape samples which ribbons could not perform, we need a bulk specimen. In order to produce Fe-M-B bulk alloys, we must prepare amorphous alloy powders first. Then we consolidate amorphous alloy powders to bulky forms.

Mechanical alloying (MA) is an effective way to synthesize amorphous alloy powders in mass production.⁵ However, the amorphous forming composition range of MA is different from rapid quenching. From our previous work,⁶ we obtained an almost completely amorphous phase when the value of Fe atoms is less than 77 at. %. If the percentage of Fe exceeds 85 at. %, there would be no completely amorphous phase.

Here, we report on the microstructure changes of mechanically alloyed amorphous $\text{Fe}_{80}\text{Zr}_8\text{B}_{11}\text{Cu}_1$ samples during annealing.

II. EXPERIMENTAL PROCEDURE

Besides elemental powders of Fe (>98%) and Cu (99.5%, ~200 mesh), ingots of Fe-Zr (Zr 75%) and Fe-B (B 20%) binary systems were used as starting materials. Ingots of Fe-Zr and Fe-B were crushed with a pulverizer and the resulting powders were sifted out. Then, the powders were mixed to give the desired composition as $\text{Fe}_{80}\text{Zr}_8\text{B}_{11}\text{Cu}_1$ and sealed in a cylindrical stainless steel container under an Ar

atmosphere. The MA was performed in a planetary ball mill with a ball to powder weight ratio of 40:1 and a speed of 160 rev min^{-1} . The diameter of the hardening balls was 9.6 mm. A little methanol was used to prevent excessive welding in the chamber thus allowing a high degree of mixing.

The mechanically alloyed powders were annealed for 1 h at various temperatures ranging from 673 to 1173 K inside a sealed vacuum tube below 10^{-4} Torr.

The x-ray diffraction patterns were obtained using Cu $K\alpha$ radiation of a Dmax-rA diffractometer equipped with a graphite monochromator. The microstructure of the samples was characterized by transmission electron microscopy (TEM) using JEOL 2000. The Mössbauer spectra of the studied samples were performed at room temperature in the transmission geometry using a conventional constant acceleration spectrometer and a $^{57}\text{Co-Pd}$ source of 50 mCi. Saturation magnetization was measured in a vibrating sample magnetometer (model 155-1).

III. RESULTS AND DISCUSSION

Figure 1 shows the change of x-ray diffraction patterns as a function of annealing temperature for a 72 h mechani-

FIG. 1. X-ray diffraction patterns of a mechanically alloyed $\text{Fe}_{80}\text{Zr}_8\text{B}_{11}\text{Cu}_1$ alloy at different annealing temperatures.

FIG. 2. TEM micrograph (a) and diffraction pattern (b) of a mechanically alloyed $\text{Fe}_{80}\text{Zr}_8\text{B}_{11}\text{Cu}_1$ sample.

cally alloyed $\text{Fe}_{80}\text{Zr}_8\text{B}_{11}\text{Cu}_1$ alloy. The sample milled for 72 h consists only of a diffuse peak. In Fig. 2, the TEM micrograph and diffraction pattern of milled powder reveal the formation of an amorphous phase. When annealed at 673 K, this diffuse peak becomes sharp. Upon annealing at 873 K, the α -Fe phase becomes significant, and no other crystalline states exist. When the annealing temperature reaches 1173 K, a few newly precipitated phases as well as a bcc phase are observed. This phenomenon is similar to other quenched samples.^{7,8}

The lattice parameter of the bcc phase is measured to be 0.2868 nm at 873 K and 0.2884 nm at 1173 K and there is a tendency to increase with increasing annealing temperature. The lattice parameter at 1173 K is larger than 0.2866 nm for pure α -Fe, indicating that some solute elements are dissolved into the α -Fe phase. It could be concluded that when the annealing temperature reaches 1173 K, in addition to some Zr and B elements precipitating in the form of ZrB_2 , the rest have been dissolved into the bcc phase. This result is different from the report⁸ that the increase of annealing temperature results in a mixed structure of α -Fe and $\text{Fe}_3(\text{Zr}, \text{B})$ phase for an as-quenched amorphous $\text{Fe}_{91}\text{Zr}_7\text{B}_2$ alloy.

Figure 3 shows the TEM microstructure of a $\text{Fe}_{80}\text{Zr}_8\text{B}_{11}\text{Cu}_1$ alloy annealed at 673 K. It is clear that there is a new phase well distributed in an amorphous base. Combined with the x-ray diffraction result, we know that this new phase must be an α -Fe (Zr, B) bcc phase. Further raising the temperature to 873 K causes a bcc phase increase. It could be

FIG. 3. TEM micrograph of a mechanically alloyed $\text{Fe}_{80}\text{Zr}_8\text{B}_{11}\text{Cu}_1$ sample after annealing at 673 K.

FIG. 4. Dark-field electron micrograph (a) and diffraction pattern (b) of a mechanically alloyed $\text{Fe}_{80}\text{Zr}_8\text{B}_{11}\text{Cu}_1$ sample after annealing at 873 K.

seen from the dark-field electron micrograph in Fig. 4(a). The dimension of this phase is about 15 nm. The selected area diffraction pattern corresponding to Fig. 4(a) is shown in Fig. 4(b).

In Fig. 5, we present saturation magnetization as a function of annealing temperature. It is apparent that the saturation magnetization increases with the annealing temperature, corresponding to the increase of α -Fe (Zr, B) during annealing.

In Fig. 6, we present the fitted Mössbauer spectra at room temperature milled for 72 h and all the annealed samples of $\text{Fe}_{80}\text{Zr}_8\text{B}_{11}\text{Cu}_1$. From x-ray diffraction patterns, there seems to be few crystalline phases in the $\text{Fe}_{80}\text{Zr}_8\text{B}_{11}\text{Cu}_1$ sample milled for 72 h. But we could see from Fig. 6 that there is clearly part of a crystalline phase in this sample. With the increase of annealing temperature, the crystallization part also increases. Upon annealing at 1173 K, the amorphous phase no longer exists, as shown in Fig. 6.

Figure 7 is the hyperfine field distributions of the amorphous phase corresponding to the Mössbauer spectra shown in Fig. 6. In hyperfine field distribution patterns, there are two clear peaks, representing two different sites of the iron atoms with different short range orders.^{9,10} In Table I, we present the results of the average magnetic hyperfine field, corresponding to the two different amorphous phases, \bar{H}_1 and

FIG. 5. Saturation magnetization as a function of annealing temperature.

TABLE I. Average magnetic hyperfine field, \bar{H}_1 , \bar{H}_2 , and \bar{H} , σ_1/σ_2 of two different amorphous phases and percentages of α -Fe(Zr,B) at different annealing temperatures.

Annealing temperature (K)	\bar{H}_1 (T)	\bar{H}_2 (T)	σ_1/σ_2	\bar{H} (T)	% α -Fe (Zr,B)
Milled	6.0	13	1.3	9.0	23
673	5.4	12	0.8	9.1	25
873	5.3	18	0.6	13.2	61

\bar{H}_2 , and the total amorphous phases, \bar{H} . We also present the calculated ratios of Fe atoms in two amorphous phases, σ_1/σ_2 , as well as percentages of α -Fe (Zr,B) for the samples milled for 72 h and annealed at 673 and 873 K. It reveals that, with the increase of annealing temperature, the relative value of amorphous phase 2 and the average magnetic hyperfine field for the total amorphous phase increase, but the average magnetic hyperfine field for amorphous phase 1 decreases slightly. Further, the percentage of bcc phase increases with increasing annealing temperature.

IV. SUMMARY

An amorphous $\text{Fe}_{80}\text{Zr}_8\text{B}_{11}\text{Cu}_1$ sample has been formed by mechanical alloying after 72 h milling and then annealed at a different temperature. With the increase of temperature, the bcc phase precipitates from the amorphous base. Upon annealing at 873 K, the percentage of the bcc part will be 61%. When annealed at 1173 K, the amorphous phase completely converts into an α -Fe solution and a small ZrB_2 phase. Furthermore, Mössbauer spectroscopy reveals that there are two short range orders in the amorphous phase at different temperatures.

Microstructure and magnetic properties of $\text{Cu}_{0.8}(\text{Fe}_{1-x}\text{Co}_x)_{0.2}$ alloy powders manufactured by a mechanical alloying process

Yong Goo Yoo and Seong Cho Yu

Department of Physics, Chungbuk National University, Cheongju 360-763, Korea

Won Tae Kim

Rapidly Solidified Materials Engineering Research Center, Department of Physics, Chongju University, Chongju 360-764, Korea

Changes in structural and magnetic properties during mechanical alloying and heat treatment were studied in $\text{Cu}_{0.8}(\text{Fe}_{1-x}\text{Co}_x)_{0.2}$ ($x=0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6$) alloys using x-ray diffractometry, transmission electron microscopy, and magnetometry. Supersaturated solid solutions with a fcc crystal structure were obtained in all alloys by mechanical alloying. The grain sizes of the solid solutions were about 20 nm. Magnetization of the supersaturated solid solutions could be explained by a mixture of two types of particles showing paramagnetism and ferromagnetism. The variation in magnetization with Co content in the solutions was similar to the Slater–Pauling curve. Fe–Co with a bcc structure precipitates during annealing of the $\text{Cu}_{0.8}\text{Fe}_{0.1}\text{Co}_{0.1}$ alloy. With increasing annealing temperature ferromagnetic behavior becomes dominant due to a coarsening of the precipitates. © 1996 American Institute of Physics. [S0021-8979(96)31308-6]

I. INTRODUCTION

Mechanical alloying at low temperatures has been used to prepare metastable phase alloys, such as supersaturated solid solutions or amorphous phase powders from elemental or intermetallic powders in many alloy systems.^{1–5} Much work has been done to produce a metastable solid solution in immiscible alloy systems such as Fe–Cu,^{1–4} Cu–Co,⁵ and Cu–Fe–Co.⁶ Structural evolution and magnetic property changes during mechanical alloying have been studied.

In this study, $\text{Cu}_{0.8}(\text{Fe}_{1-x}\text{Co}_x)_{0.2}$ ($x=0.0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6$) alloys were selected to produce a supersaturated solid solution and then precipitate ferromagnetic particles in a nonmagnetic Cu matrix by subsequent heat treatment. The content of the ferromagnetic components was fixed at 0.2 to prevent the rapid growth of precipitates and prevent contact between particles during heat treatment. The alloy system was also selected because Fe–Cu and Co–Cu are immiscible systems whereas Fe–Co is miscible. Changes in microstructure and magnetic properties during mechanical alloying and postheat treatment were studied using x-ray diffractometry, transmission electron microscopy, and magnetometry.

II. EXPERIMENT

The chosen compositions were $\text{Cu}_{0.8}(\text{Fe}_{1-x}\text{Co}_x)_{0.2}$ ($x=0.0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6$). Mixtures of the appropriate amounts of Fe, Cu, and Co (–80 mesh, 99.9%) powders were mechanically alloyed using a SPEX 8000 mixer and mill with stainless steel balls and vial. Mechanical alloying was performed under an Ar atmosphere with a ball-to-powder ratio of 6:1. The processing time varied from 1 to 24 h to observe structural changes during the process. Heat treatment was performed in a vacuum of 10^{-3} Torr for 1 h at various temperatures between 573 and 673 K. The progress of structural change during mechanical alloying was studied by using x-ray diffraction (XRD) with $\text{Mo } K_\alpha$ radiation. Grain size in mechanically alloyed powders was estimated from the XRD profiles by using a Williams–Hall plot. The

microstructure was observed in a CM 30 transmission electron microscope operating at 200 kV. Variation of magnetization with processing time was measured at room temperature and at 77 K using a vibrating-sample magnetometer with a maximum applied field (H) of 10 kOe. Also a superconducting quantum interference device (SQUID) magnetometer was used to measure magnetization at 5 K with a maximum magnetic field of 20 kOe.

III. RESULTS AND DISCUSSION

A. Structural change

Figure 1(a) shows XRD patterns obtained from $\text{Cu}_{0.8}\text{Fe}_{0.1}\text{Co}_{0.1}$ alloys for various processing times. An XRD pattern from as-mixed powders could be separated into a mixture of diffraction peaks from bcc Fe, fcc Cu, hcp Co, and fcc Co. The elemental Co powders used here were a mixture of fcc and hcp Co crystals. With increasing processing time, the diffraction peaks from Co disappeared first, peaks from Cu and Fe became weak and broad, and peaks from bcc Fe finally disappeared. All the XRD peaks from powders mechanically alloyed for 24 h had a fcc structure, indicating the formation of a supersaturated solid solution. A supersaturated fcc solid solution was obtained in all alloys after mechanical alloying for 24 h. The grain size of the supersaturated solid solution, calculated from the XRD patterns of the Williams–Hall plot,⁷ was about 20 nm and independent of Co content. With increasing Co content, the lattice parameter of the solid solutions decreased due to the substitution of smaller Co atoms for larger Fe atoms, again indicating the formation of solid solution.

Figure 1(b) shows XRD patterns obtained from $\text{Cu}_{0.8}\text{Fe}_{0.1}\text{Co}_{0.1}$ powders heat treated for 1 h at 573 and 623 K. When compared with XRD patterns from the as-mechanically-alloyed sample shown in Fig. 1(a), it can be seen that extra peaks appeared due to the decomposition of the metastable supersaturated solid solution. All of the additional peaks could be analyzed as a bcc Fe–Co solid solu-

FIG. 1. X-ray diffraction profiles from $\text{Cu}_{0.8}\text{Fe}_{0.1}\text{Co}_{0.1}$ powders; (a) processed for 0, 6, 24 h, (b) and then annealed for 1 h at 573 and 623 K.

tion. In melt-spun $\text{Cu}_{0.8}\text{Co}_{0.15}\text{Fe}_{0.05}$ alloys, fcc Co has been reported to precipitate during heat treatment at low temperatures while the bcc Fe-Co solid solution precipitates at higher temperatures. The precipitation of the Fe-Co phase in the mechanically alloyed sample, as opposed to the separate precipitation of Co and Fe, may result from accumulated strain and high dislocation densities in the mechanically alloyed powders, which are typically about 0.5% and $10^{16}/\text{m}^2$, respectively.⁴ The driving force for precipitation of bcc Fe-Co is larger than that for separate precipitation due to a negative heat of mixing in the Fe-Co system.

Figures 2(a) and 2(b) show the bright field and selected area diffraction patterns (SADP), respectively, from $\text{Cu}_{0.8}\text{Fe}_{0.1}\text{Co}_{0.1}$ powders processed for 24 h. Figures 2(c) and 2(d) show a corresponding micrograph and SADP, respec-

FIG. 2. Bright-field image and selected area diffraction pattern from $\text{Cu}_{0.8}\text{Fe}_{0.1}\text{Co}_{0.1}$ powders, (a) and (b): as-mechanically alloyed for 24 h, (c) and (d): mechanically alloyed for 24 h and heat treated for 1 h at 593 K.

FIG. 3. Variation in magnetization of $\text{Cu}_{0.8}(\text{Fe}_{1-x}\text{Co}_x)_{0.2}$, mechanically alloyed for 24 h as a function of Co content.

tively, from $\text{Cu}_{0.8}\text{Fe}_{0.1}\text{Co}_{0.1}$ processed for 24 h and then heat treated for 1 h at 593 K. The grain size of the as-mechanically alloyed specimen was measured from the bright-field image to be about 20 nm. Due to the small grain size and high dislocation density, the grain boundary in the bright-field image is not clear. The SADP from the as-mechanically alloyed sample shows only a sharp fcc ring pattern, in agreement with the XRD. The bright-field image of the heat-treated sample shows 5 nm precipitates, as marked by arrows, in a Cu matrix. The Cu grain size is slightly larger than that in the as-mechanically alloyed sample. The SADP from the heat-treated specimen shows not only a sharp fcc ring pattern but also extra dim rings. These extra rings (marked by arrows) can be analyzed as being from a bcc crystal structure. No rings appeared from fcc Co particles, indicating that the bcc phase is a solid solution of Fe-Co, again in agreement with the XRD diffraction study. Thus, the small precipitates seem to be a bcc Fe-Co phase.

FIG. 4. Variation in magnetization of $\text{Cu}_{0.8}\text{Fe}_{0.1}\text{Co}_{0.1}$ powders, mechanically alloyed for 24 h, at 5 K. The solid line represents the fits of Eq. (1).

FIG. 5. Hysteresis loops measured from $\text{Cu}_{0.8}\text{Fe}_{0.1}\text{Co}_{0.1}$ alloys, mechanically alloyed for 24 h and heat treated for 1 h at different temperatures.

B. Magnetic properties

Figure 3 shows the variation of magnetization, measured at room temperature with an external field of 1 T, of $\text{Cu}_{0.8}(\text{Fe}_{1-x}\text{Co}_x)_{0.2}$ mechanically alloyed for 24 h, as a function of Co content. Magnetization of the alloys increases with Co content and reaches a maximum at about $x=0.3$ of Co fraction, and then decreases with a further increase of Co content. The variation of magnetization with Co content is in agreement with the Slater–Pauling curve.⁸

Figure 4 shows the magnetization curve for the mechanically alloyed $\text{Cu}_{0.8}\text{Fe}_{0.1}\text{Co}_{0.1}$ alloy, measured at 5 K by using a SQUID magnetometer. The magnetization does not saturate under the maximum field of 20 kOe. The curve was fit with a two component function representing the sum of the ferromagnetic component and a paramagnetic component, which is used by Rubinstein *et al.*⁹

$$\frac{M(H)}{M_s} = (1 - \alpha) \left[1 - \exp\left(-\frac{H}{H_s}\right) \right] + \alpha \tanh\left(\frac{BH}{T}\right). \quad (1)$$

The first and second components of the equation represent ferromagnetic and paramagnetic contributions, respectively, where α is the fraction of paramagnetic contribution and H_s and M_s are the saturation field and saturation magnetization, respectively. B is an adjustable parameter. The solid line in

Fig. 4 is the plot of Eq. (1) with $\alpha=0.33$ and $H_s=1200$ Oe, and the ferromagnetic and paramagnetic components are also included in Fig. 4 for comparison. The analysis indicates that about 33% of the magnetization results from paramagnetic components. Therefore, the magnetization behavior of the mechanically alloyed powders can be explained by a mixture of ferromagnetism and paramagnetism.

Figure 5 shows the hysteresis loops measured at room temperature from $\text{Cu}_{0.8}\text{Fe}_{0.1}\text{Co}_{0.1}$ specimens, annealed for 1 h at different temperatures. With increasing annealing temperature, magnetization increased due to coarsening of the magnetic particles. However, magnetic saturation was still not obtained. The increases in magnetization and coercivity in heat-treated samples indicate that the ferromagnetic component becomes increasingly dominant due to the coarsening of the magnetic particles.

IV. CONCLUSION

Supersaturated fcc solid solutions, with grain sizes of about 20 nm, were prepared by mechanical alloying $\text{Cu}_{0.8}(\text{Fe}_x\text{Co}_{1-x})_{0.2}$ ($x=0.0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6$) powders. The variation in magnetization with Co content in these supersaturated ternary solid solutions was similar to the Slater–Pauling curve. The magnetization behavior of the supersaturated solid solutions showed a mixture of ferromagnetic and paramagnetic behavior. Heat treatment of the supersaturated solid solutions resulted in the precipitation of the bcc Fe–Co phase and the ferromagnetic behavior becoming increasingly dominant as the annealing temperature was increased.

We report on the preparation, by high energy ball milling and starting from an amorphous melt-spun material, of powdered samples exhibiting, after suitable thermal treatments, saturation coercive forces of the order of a few tens of mOe. © 1996 American Institute of Physics. [S0021-8979(96)31408-2]

I. INTRODUCTION

Soft magnetic behavior, i.e., the simultaneous occurrence of high initial susceptibility and reduced coercive force, is linked to the occurrence, in a specific material, of particular structural and microstructural characteristics. Among these characteristics, the most relevant ones are a low value of the effective magnetic anisotropy (including magnetoelastic contributions) and the absence of large fluctuations of both the intrinsic (magnetization, exchange) and extrinsic (defects in a generalized sense and some morphological features such as grain size, and shape) properties. The low anisotropy values favor both magnetization rotation and the nucleation processes, and the homogeneity is linked to the absence of hindrances to domain wall displacement.

The reduction of the effective magnetic anisotropy is achieved either by the combination of a low structural (magnetocrystalline) anisotropy with a large degree of texture (electrical steels)¹ or through the exchange induced average over long distances of the coupling of the magnetization with the local structure (the atomic short range order crystalline field and local easy axes in the particular cases of the transition metal-metalloid amorphous alloys² and the so-called nanocrystalline materials,³ respectively).

There exist a variety of techniques to obtain soft magnetic materials, but most of the research effort and industrial interest are centered on the different implementations of the melt spinning and the in-rotating-water quenching methods since both allow the production of soft materials (ribbon and wire, respectively) in a continuous way and with highly controlled and perfect morphologies. The ribbon and wire geometries are very satisfactory for a range of applications, such as sensors and pulse generators, but are not the best (the actually achieved thicknesses and diameters are lower than 200 μm) for those in which large mass or volume of soft material or complexly shaped soft parts are required.

In this context, the solid state reaction techniques in which the possibility of amorphization is not limited by the relationship between the cooling rate and the transverse dimensions, represent a relevant alternative. Among these techniques those having a greater potential for use are mechanical alloying (MA) and mechanical grinding (MG) since they combine the possibility of phase formation (in MA) or phase transformation (in MG) with a product material which is in

powdered form, and therefore is suitable for compaction and densification in a variety of shapes.

In the present work we will present results about the nanocrystallization by MG of an amorphous melt-spun alloy and report on the development, through relaxation-type thermal treatments, of magnetic softness in the ground material.

II. PREPARATION OF SAMPLES AND EXPERIMENTAL TECHNIQUES

The samples were prepared by mechanical grinding of a precursor melt-spun material having a nominal composition of $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$. The ribbons were cut into small pieces of ~ 5 mm transverse dimension. These pieces were sealed, under an Ar atmosphere, in a hard stainless steel jar (having an inner diameter of 50 mm) together with four hard stainless steel balls (each having an 8 mm diam and in a mass of precursor material to mass of the balls ratio of 1:10) and milled in a Fritsch Pulverisette 7 mill for 1–3 h. The phase distribution of both the precursor material and the milled product was examined by means of x-ray diffraction (XRD, CuK_α) and their thermal stability and crystallization processes were investigated by differential scanning calorimetry (DSC—all the thermograms were taken in a continuous heating mode at a constant rate of 40 K min^{-1}). The DSC unit was also used to thermally treat the samples after which their coercivity was measured in a low field extraction magnetometer. Considering the shape of the samples used for the magnetic measurements (pressed powder pellets 3 mm in diameter and 3 mm in height), their coercivity was measured by means of a zero drift integrating unit after saturating the samples in 20 kOe field.

III. RESULTS AND DISCUSSION

The milling process reduced the starting melt-spun material pieces to powder form. The compromise, typical of ball milling, between particle fracture and particle welding led in our particular case to the attainment, after 1 h of milling, of particles having an average transverse dimension of 35 μm . This should be an equilibrium particle size since, in the milling time range we explored, we were not able to detect any variation of this average dimension.

Figure 1 presents the XRD diffractograms measured in the precursor material [Fig. 1(a)] as well as in the as-milled samples [for 1, 2, and 3 h of milling; see Figs. 1(b), 1(c), and 1(d), respectively]. Figure 1 shows that the precursor mate-

FIG. 1. XRD patterns obtained in the (a) amorphous precursor, (b) 1 h milled sample, (c) 2 h milled sample, and (d) the 3 h milled sample.

rial has an amorphous structure and that, as the milling time increases, the corresponding as-milled samples develop some crystalline reflections at positions indistinguishable from those corresponding to α -Fe, indicating the occurrence of partial crystallization and an increase of the average grain size associated with the increase of the milling time. The average grain sizes, evaluated using the method of Scherrer after subtracting from the diffractograms the precursor material halo and carrying out corrections for the instrumental broadening, were 5, 9, and 12 nm in the samples milled for 1, 2, and 3 h, respectively.

The DSC thermograms obtained both in the precursor material and in the as-milled samples are shown in Fig. 2. Similar to previous reports,⁴ the crystallization of the starting amorphous material proceeds through two distinguishable exothermic processes: one at 843 K, identified as a primary crystallization (yielding nanograins of a solid solution of Si in Fe) and one at 973 K, a pseudoeutectic crystallization associated with the precipitation of Fe_2B (this second stage was not completely developed in our thermograms). The accomplishment of partial crystallization during the milling process is evidenced by the measurement of the enthalpy per unit mass associated with the first crystallization stage: 1.3×10^9 , 5.3×10^8 , 4.8×10^8 , and 4.6×10^8 ergs/g in the case of the amorphous precursor, 1, 2, and 3 h milled samples, respectively.

Despite the presumably large percentage of amorphous phase present in the milled samples, their coercive forces were of the order of several Oe, i.e., clearly higher than those measured in the unmilled amorphous samples. We attribute this to the combination of two different mechanisms: (1) the induction of magnetoelastic anisotropies linked to the

FIG. 2. DSC thermograms measured in the (a) amorphous precursor, (b) 1 h milled sample, and (c) the 2 h milled sample.

FIG. 3. Treatment time dependence of the coercivity of the 1 h milled samples annealed at different temperatures.

stresses built-in during the grinding process, and (2) the presence of hindrances to the domain wall motion, which could be related to the weak coupling of the crystallites to the amorphous phase. To relax these large as-milled coercivities we submitted the samples to thermal treatments carried out, in all the cases, by continuously heating the samples at a rate of 40 K min^{-1} up to a given temperature, T_{ann} ($T_{\text{ann}} = 625$, 665 , 675 , and 725 K , i.e., always well below the peak temperature of the first crystallization stage), keeping the samples at that temperature for a time t_{ann} (in the range from 0 to 12 min) and then quenching them at a rate of 200 K min^{-1} . The coercive force values measured after these anneals in the 1 h milled sample are plotted in Fig. 3. The best treatment parameters corresponded to $T_{\text{ann}} = 665 \text{ K}$ and $t_{\text{ann}} = 4 \text{ min}$, which reduced the coercive force to a value of $0.091 \pm 0.004 \text{ Oe}$. The results corresponding to the relaxation of the 2 h milled sample are presented in Fig. 4. These results have a similar evolution with t_{ann} to those presented for the 1 h milled sample. The only remarkable difference of the occurrence was a broad minimum in the curve corresponding to annealing at 675 K . Particularly, by annealing the sample at this temperature for 6 min we got a coercivity value of $0.055 \pm 0.004 \text{ Oe}$. Relaxation did not proceed to that extent in the 3 h milled sample (Fig. 5) where, almost independent of T_{ann} , a minimum coercive force value of the order of 0.3 Oe was reached after 6–8 min of annealing.

The evolution with the treatment parameters of the phase distribution of the ground samples is illustrated in Fig. 6, where the XRD results obtained in the 2 h milled, 675 K , 6 and 12 min annealed samples are compared to the diffractograms corresponding to the as-milled materials. According to these results, the short time treatments (those leading to co-

FIG. 4. Treatment time dependence of the coercivity of the 2 h milled samples annealed at different temperatures.

FIG. 5. Treatment time dependence of the coercivity of the 3 h milled samples annealed at different temperatures.

ercivity decrease) do not produce any observable change in the diffractograms whereas anneals carried out at times longer than that corresponding to the minimum resulted in clear grain growth. This was confirmed by the measurement in the 675 K, 6 min annealed sample of an enthalpy per unit mass associated to the first crystallization stage of 4.4×10^8 ergs/g, which is almost identical to the as-milled sample value.

IV. CONCLUSIONS

Ball milling of the melt-spun ribbon-shaped material resulted in micron-sized powders in which the first crystallization stage was partially accomplished and which exhibited high coercivities. Thermal treatments of the as-milled samples produced a remarkable coercivity relaxation which (as shown in Fig. 7) led to optimum values for temperatures in the range from 665 up to 675 K and short time treatments

FIG. 7. Treatment temperature dependence of the coercivity of the 2 h milled samples annealed for 6 and 8 min.

of the order of 6–8 min. Considering the fact that there was no detectable difference between the phase distributions of the as-milled and the optimum treated material we suggest that coercivity relaxation was related to stress relaxation in the amorphous part of the samples and to a (chemical) homogenization process taking place at the grain boundaries. These resulted in a better coupling of the crystalline nanograins with the amorphous matrix. Under these conditions, and considering the differences between the average grain size and the domain wall thickness, uniformly distributed nanosized grains weakly interact with thick domain walls. Our suggestion about the role of weakly coupled crystallites as pinning centers is supported by the fact that the minimum coercivity we were able to achieve was obtained in the 2 h milled sample despite the presumably larger value of the stresses residual to the preparation process compared to the 1 h milled sample. We identify grain growth (up to dimensions at which the grain size is comparable to the domain wall thickness) as the origin of the coercivity increase associated with the long time anneals.

Correlation of magnetic and mechanical properties of hydrogenated, compositionally modulated, amorphous Fe₈₀Zr₂₀ films (abstract)

S. Rengarajan, E. J. Yun, B. H. Lee,^{a)} B. I. Cho,^{b)} and R. M. Walser
IIUCR Center for Magnetism, University of Texas at Austin, Austin, Texas 78712

Recent research has demonstrated that large amounts of hydrogen can be electrolytically incorporated in amorphous, compositionally modulated (CM) FeZr films.¹ The first irreversible changes in the magnetic state of an electrolytically hydrogenated iron-rich amorphous alloy were observed. The hydrogen-induced changes in the magnetization were interpreted in terms of specific structural rearrangements. In this work, simultaneous measurements of the variations in the magnetization and mechanical properties of these films were measured as a function of hydrogen charging to further clarify the hydrogen-induced structure changes. The Young's moduli E and internal friction d of as-deposited, and as-hydrogenated CM Fe₈₀Zr₂₀ thin films were calculated from the displacements of a vibrating composite cantilever, measured using a laser heterodyne interferometer (LHI) having a displacement sensitivity of $\sim 0.01 \text{ \AA}$.² E and d were measured using the resonant frequency method.³ CM films with thickness 1390 \AA and modulation wavelength $\sim 10 \text{ \AA}$ were deposited on glass cantilevers (5 mm long, 2 mm wide, and $150 \text{ }\mu\text{m}$ thick) by sequentially sputtering (rf diode) elemental Fe and Zr targets. The samples were electrolytically hydrogenated for various times in 2 N phosphoric acid with a current density of 26.3 mA/cm^2 . The maximum change in magnetization of the film (from 71.5 to 551 emu/cm³) was observed after 5 min. During this time, E increased 18-fold from 535 GPa to 9.63 TPa. The unusually high Young's modulus of the as-deposited CM film is comparable to those previously observed in other CM films.⁴ The change is three times larger than the change in the E of carbon steel at the martensitic transformation, and nine times larger than the hydrogen induced increase in E of pure single crystals of iron. The d of the cantilever resonance decreased with hydrogenation, indicating that the incorporated H reduced the internal friction of the CM film. Preliminary analysis of the results indicates that the mechanical and magnetic changes can be interpreted in terms of similar atomic scale changes. Measurements on films with different CM wavelengths are in progress. © 1996 American Institute of Physics. [S0021-8979(96)82408-2]

Application of Co-based amorphous ribbon to a noise filter and a shielded cable

Osamu Ishii, Masakatsu Senda, Koji Takei, Yasuhiro Koshimoto, and Toshinori Mori^{a)}
NTT Interdisciplinary Research Laboratories, Tokai, Ibaraki 319-11, Japan

This paper describes the application of a Co-based amorphous alloy ribbon to a common-mode noise filter in the 1 MHz–1 GHz frequency range. Its saturation magnetization, and relative permeability were 6000 G and 1450, respectively. The 10- μ m-thick amorphous ribbon exhibits high loss characteristics. The resistance of a 2-mm-diam roll of amorphous ribbon (12.5 mm wide and 30 cm long) increases from 3 Ω at 1 MHz to 50 Ω at 350 MHz. It is confirmed that a filter 1/17th the volume of a conventional (ferrite core) filter exhibits the same noise attenuation. Moreover, the noise emission from a twisted pair cable is greatly reduced without any increase in the cable volume by employing the amorphous ribbon as a shielding material. © 1996 American Institute of Physics. [S0021-8979(96)74008-7]

INTRODUCTION

Electromagnetic interference (EMI) is a growing problem with electronic equipment.¹ A large amount of EMI is caused by radiated emission which is due to the common-mode noise current in the cables used to connect digital equipment. Noise emissions from cables are prevented by using common-mode noise filters. A conventional noise filter consists of a cylindrical ferrite core through which a cable is passed. In this configuration, the ferrite core absorbs the magnetic field caused by common-mode noise current in the MHz–GHz frequency range. The ferrite cores, however, are too large to allow circuit boards or circuit units to be housed compactly.

Several investigations have been undertaken on magnetic thin films² and magnetic amorphous flake³ in order to realize high loss characteristics and a large attenuation for common-mode noise in this frequency range. Senda *et al.*, reported that the thickness and magnetic anisotropy of soft magnetic films can be designed so that the film exhibits a large eddy-current loss.⁴ This paper describes the application of Co-based amorphous alloy ribbon to an EMI noise filter which is much smaller than a ferrite core. The ribbon is also applied as the shielding material for a shielded twisted pair cable thus reducing the noise emission.

EXPERIMENT

The 10- μ m-thick and 12.5-mm-wide amorphous ribbon (ACO-5, Hitachi Metals, Ltd.) was prepared by the roll cooling method. The ribbon was designed to have zero magnetostriction (nominal composition: $\text{Co}_{68.59}\text{Fe}_{1.28}\text{Mo}_{2.57}\text{Mn}_{3.7}\text{Si}_{4.66}\text{B}_{9.2}$) in order to maintain its high permeability when wound around cables. The magnetic

properties of the ribbon, which were measured with a B-H loop tracer, are listed in Table I. The specific resistance was 120 $\mu\Omega$ cm.

Its impedance was measured from 1 MHz to 1 GHz with an impedance meter. The sample consisted of a 30-cm-long amorphous ribbon wound around a 16-mm-long current lead, with a sheath diameter of 2 mm.

Figure 1 shows the noise current measurement setup. The transmission characteristics of the cables were measured from 1 MHz to 1 GHz with a network analyzer. We used 130-cm and 210-cm-long twisted pair cables with a characteristic impedance of 110 Ω . One end of the cable was connected to port 1 of a network analyzer via an impedance matching circuit and the other end was terminated with a resistance of 110 Ω . A section of cable at the input end was wrapped with the amorphous ribbon which was attached with organic paste. The total volume of the amorphous ribbon was 0.225 cc (ribbon length: 180 cm). A commercially available ferrite core (inner diameter: 9 mm, outer diameter: 16 mm, length: 28 mm, volume: 4 cc) was also used for comparison. Common-mode noise current, which is equivalent to the transmitted power, S_{21} , was detected with a current probe.

Figure 2 shows the radiated noise field measurement setup. A digital signal generator whose clock frequency was 4 MHz and a receiver were housed in a shield case and connected with 3-m-long shielded twisted pair cable. This was all placed on a turntable. The radiated noise power was received by a biconical antenna (30–300 MHz) or a log-

periodic antenna (300–1000 MHz) which was placed 3 m away from the shield case at a predetermined height of 1 m or 4 m. The horizontal and vertical electromagnetic polarization spectra were measured with a spectrum analyzer at both heights for all azimuth angles. In the spectrum where the strongest radiation peak was obtained, the 20 strongest peaks (harmonics of the clock signal) were averaged to obtain the noise intensity. This measurement was carried out in a radio wave anechoic chamber.

RESULTS AND DISCUSSION

Figure 3 shows the frequency dependence of the impedance ($Z = R + iX$) for a 30-cm-long amorphous ribbon. The reactance, X , has a broad peak of $\sim 10 \Omega$ at around 5 MHz and then drops to 0Ω at 200 MHz. The resistance, R , increases from 3Ω at 1 MHz to 50Ω at 350 MHz with increasing frequency. R is larger than X above 5 MHz. The impedance, Z , of a magnetic cylinder (l : length, t : thickness, r : inner diameter) is

$$Z = (2\pi f \cdot \mu r \cdot \mu o \cdot l \cdot t) / (2\pi r),$$

where f , μo , and μr are the frequency, the permeability of a vacuum, and the relative permeability ($\mu r = \mu r' - i\mu r''$) of the cylinder, respectively.² As the imaginary part of the relative permeability, $\mu r''$, increases, the R value also increases. According to the eddy-current loss theory, $\mu r''$ approaches $\mu r'$ at a thickness of $2-3\delta$, where δ is the skin depth.⁵ This means that R approaches X at a thickness of $2-3\delta$. The fact that R is larger than X above 5 MHz is qualitatively consis-

FIG. 3. Frequency dependence of the impedance ($Z = R + iX$) for a 30-cm-long amorphous ribbon.

tent with the eddy-current loss theory, because the thickness of the amorphous ribbon is calculated to be about 2δ at 5 MHz. Hence, the amorphous ribbon is expected to exhibit a large noise attenuation above 5 MHz. In fact, the tendency of R to increase with frequency is very similar to that of a conventional ferrite core, whose R value ranges from several tens of Ω in the MHz region to several hundred Ω in the GHz region. The maximum R value estimated for six rolls (180 cm long) of amorphous ribbon is about 300Ω above 350 MHz, which is almost the same as that of the ferrite core. Consequently, the six rolls of amorphous ribbon were considered to have the same noise attenuation potential as the ferrite core.

Figure 4 shows the frequency dependence of S_{21} for the 130 cm long cables on which the six rolls of amorphous ribbon or the ferrite core were attached. Since the cable operates as an antenna for common-mode noise current, both the noise emission and noise attenuation are enhanced at the resonant frequency (50 MHz) and at higher harmonic frequencies. The noise attenuation of the amorphous ribbon rolls was 15 dB at 50 MHz which is almost the same as the ferrite core.

Figure 5 shows the frequency dependence of s_{21} for the 210-cm-long cables with either the six rolls of amorphous ribbon or the ferrite core attached. Also in this configuration,

FIG. 2. Schematic diagram of the radiated noise field measurement setup.

FIG. 4. Frequency dependence of S_{21} for 130-cm-long cable.

FIG. 5. Frequency dependence of S_{21} for 210-cm-long cable.

both the noise emission and noise attenuation are enhanced at the resonant frequency (30 MHz) and at higher harmonic frequencies. The noise attenuation of the amorphous ribbon rolls (~ 16 dB at 30 MHz) is almost the same as that of the ferrite core. Since the noise attenuation values of the six amorphous ribbon rolls for the 130-cm and 210-cm-long cables are the same as that of the ferrite core, the amorphous ribbons enable the volume of an EMI noise filter to be reduced to 1/17th that of a ferrite core.

Another advantage of the amorphous ribbon is that it can be used as cable shielding material because of its flexibility. Figure 6 shows the radiated noise spectra from twisted pair cables;

- (a) shielded with Al foil and
- (b) shielded with amorphous ribbon.

The cable was wrapped with an average of three layers of amorphous ribbon. The radiation produced by the common-mode noise current along the cables was reduced by an average of 8 dB in the 30–1000 MHz frequency range by using amorphous ribbon rather than Al foil as the shielding material. This noise attenuation is the same as that obtained with a series of six ferrite cores. Since the total volume of the amorphous ribbon used for the shielding was 2.5 cc (~ 20 m long) which is 60% that of the ferrite core, the noise attenuation of the former is ten times larger than that of the latter. Because the noise current is distributed along a cable, the optimum loading position for the amorphous ribbon is the point at which the current is maximum. However, the noise current is reduced uniformly in the amorphous ribbon shielded cable so that the size is reduced to 1/10th that of a ferrite core. Although this improvement is not as great as that achieved with the six amorphous ribbon rolls, it should be noted that there is no change in the practical volume of the cables because the shielding was covered with plastic sheath with the same diameter. The amorphous ribbon shielded cable has a large potential for suppressing EMI

noise and realizing the high density housing of digital circuit boards and units.

CONCLUSION

10- μ m-thick Co-based amorphous alloy ribbon was confirmed to be a promising candidate for use in common-mode noise filters and as shielding material for shielded twisted pair cable. The amorphous ribbon exhibits high loss characteristics and can provide the same noise attenuation as a ferrite core with 1/17th in the volume. Moreover, the noise emission from the twisted pair cable is greatly reduced without any increase in the cable volume by employing the amorphous ribbon as a shielding material.

A gigahertz-range electromagnetic wave absorber with wide bandwidth made of hexagonal ferrite

Morihiko Matsumoto and Yoshimori Miyata

Nippon Telegraph and Telephone Corporation, NTT Technical Assistance & Support Center,
3-9-11, Midori-cho, Musashino-shi, Tokyo 180, Japan

A thin electromagnetic wave absorber has been investigated; it is composed of hexagonal ferrite and retains high permeability even in the gigahertz-range. The grid-type wave absorber composed of the hexagonal ferrite was examined to broaden the bandwidth in a gigahertz-range by introducing free space in the direction perpendicular to the electric field, which decreased total permittivity. Absorbers made of $\text{Ba}_3\text{Co}_2\text{Fe}_{24}\text{O}_{41}$ (Co_2Z) and $\text{Ba}_2(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Fe}_{12}\text{O}_{22}$ [$(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$] showed wide bandwidths of 1.8–5 GHz and 1.5–4.5 GHz (>15 dB), respectively, when the free space was 37% (v/v) and the thickness of the ferrite was about 5 mm. Increasing the free space led to a wider bandwidth: 1.7–9 GHz was achieved with a 50% (v/v) of free space when the thickness of the $(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$ was 7 mm. © 1996 American Institute of Physics. [S0021-8979(96)74108-3]

I. INTRODUCTION

Soft ferrite materials are extensively used as electromagnetic-wave absorbers. A gigahertz-range wave absorber has attracted much attention because this frequency region has recently become widely used. Two types of gigahertz-range absorbers using ferrite are commercially available: the cubic ferrite/rubber composite type and the pyramidal structure type. The former is thin (≈ 7 mm) but has a narrow bandwidth, while the latter is thick (> 100 mm) but has a wide bandwidth. The narrow bandwidth could be due to the impedance mismatch that results from ferrite possessing greater permittivity than the permeability in the gigahertz region. A grid-type wave absorber composed of cubic ferrite was developed to broaden the bandwidth by introducing free space into the ferrite in the direction perpendicular to the electric field so as to decrease the total permittivity.¹ However, this type of absorber is thick for various applications with frequencies above 1 GHz because the permeability of the cubic ferrite dramatically decreases in the gigahertz range.

We have investigated a new grid-type absorber for the gigahertz range that uses Co_2Z or $(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$ ferrite with a hexagonal crystal structure. This type of ferrite has a higher permeability in the gigahertz range than the cubic ferrite,² and is thus expected to lead to thinner wave absorbers in the gigahertz range.

We first measured the relative complex permeability ($\hat{\mu} = \mu' - i\mu''$) and permittivity ($\hat{\epsilon} = \epsilon' - i\epsilon''$) in the range from 1 MHz to 10 GHz to clarify the electromagnetic material properties of the hexagonal ferrite in the high-frequency region. We then used these $\hat{\mu}$ and $\hat{\epsilon}$ data to estimate the absorption characteristics of the grid-type wave absorber by numerical simulation based on the distributed-constant circuit model. We also directly measured the reflection loss of the absorbers to evaluate their absorption characteristics.

II. EXPERIMENT

We pressed Co_2Z and $(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$ powders into toroidal shapes and sintered them in air at 1300 °C and 1250 °C, respectively.

The $\hat{\mu}$ and $\hat{\epsilon}$ were evaluated by measuring the S_{11} and S_{21} parameters in the frequency range of 50 MHz to 10 GHz by using an HP 8720C network analyzer. We also used another HP 4291A rf impedance/material analyzer to determine $\hat{\mu}$ and $\hat{\epsilon}$ in the frequency range between 1 MHz and 1 GHz. Data from both methods were almost identical. The absorption characteristics were evaluated by measuring the S_{11} (reflection loss) of the ferrite sample backed by a metal plate. A schematic diagram of the grid-type ferrite absorber mounted in a coaxial holder is illustrated in Fig. 1. Numerical simulation was carried out from the measured values of $\hat{\mu}$ and $\hat{\epsilon}$, using 100 data points between 1 MHz and 10 GHz.

III. RESULTS AND DISCUSSION

Figure 2(a) and (b), respectively, show the frequency dependence of the real part (μ') and the imaginary part (μ'') of the relative complex permeability for a commercially available cubic ferrite/rubber composite,³ and hexagonal ferrites Co_2Z and $(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$. The hexagonal ferrites clearly have a higher permeability than that of the cubic ferrite in the range above 1 GHz, suggesting that hexagonal ferrite may lead to a thinner wave absorber for use in the gigahertz region.

Table I lists some properties of ferrite, obtained by measuring the reflection loss of a sample fully occupying the coaxial holder. A smaller matching thickness was obtained

FIG. 1. Schematic design of grid-type wave absorber mounted in a coaxial sample holder.

(a)

(b)

FIG. 2. Frequency dependence of real part (a) and imaginary part (b) of relative permeability for various ferrite-based systems.

for the hexagonal ferrite system (4.5 mm) than for the cubic ferrite system (6.7 mm), although all these systems have a similar matching-frequency region, because the hexagonal ferrite has superior high-frequency characteristics for μ' compared to the cubic ferrite (see Fig. 2). However, it should be noted that the bandwidth for all systems is narrow for many applications. This may result from the impedance mismatch due to the differences between μ and ϵ .

The relative μ' and ϵ' are plotted against frequency for Co_2Z and $(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$ systems in Fig. 3. Both systems have a constant μ' up to the dispersion frequency; then it drops drastically. In contrast, ϵ' remains nearly constant and is higher than μ' in all frequency regions. In particular, in the

TABLE I. Some properties of ferrite-based wave absorbers.

	Matching frequency (GHz)	Matching thickness (mm)	Frequency range (>15 dB) (GHz)
Co_2Z	1.8	4.5	1.3–2.3
$(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$	1.2	4.5	0.9–1.5
Rubber/cubic ferrite composite	0.9	6.7	0.7–1.1

FIG. 3. Frequency dependence of the real part of relative permeability and permittivity for various ferrite systems.

range above 1 GHz, the difference between ϵ' and μ' is considerably large, resulting in a large reflection in the gigahertz region. Therefore, ϵ' must be decreased to obtain a wave absorber with a wide bandwidth in the gigahertz region. Using the grid-type ferrite absorber is a way to reduce ϵ' and broaden the absorption bandwidth.

We first numerically simulated the reflection loss of the grid-type ferrite absorber on the basis of the measured complex permeability and permittivity of the ferrite, i.e., $\hat{\mu}_{\text{fer}}$ and $\hat{\epsilon}_{\text{fer}}$, so as to predict the matching thickness and the band contour of the reflection loss. Since free space is introduced in the direction perpendicular to the electric field and thus the direction parallel to the magnetic field, the total complex permeability, $\hat{\mu}_{\text{total}}$, and permittivity, $\hat{\epsilon}_{\text{total}}$, of the grid-type ferrite absorber can be calculated as follows:

$$\hat{\mu}_{\text{total}} = \hat{\mu}_{\text{fer}} v_{\text{fer}} + \hat{\mu}_{\text{air}} v_{\text{air}}, \quad (1)$$

$$\hat{\epsilon}_{\text{total}} = \hat{\epsilon}_{\text{fer}} \hat{\epsilon}_{\text{air}} / (\hat{\epsilon}_{\text{fer}} v_{\text{air}} + \hat{\epsilon}_{\text{air}} v_{\text{fer}}), \quad (2)$$

FIG. 4. Frequency dependence of reflection loss of Co_2Z -based grid-type wave absorber [free space 37% (v/v)].

FIG. 5. Frequency dependence of reflection loss for $(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$ -based grid-type wave absorber [free space 37% (v/v)].

where v_{fer} and v_{air} are the normalized volume of ferrite and air, respectively, in which magnetic and electric fields can pass and $v_{\text{fer}} + v_{\text{air}} = 1$.

Equation (2) shows that introducing free space in the direction perpendicular to the electric field effectively reduces ϵ'_{total} . For example, if the relative ϵ''_{fer} is very small (<0.1), the relative ϵ'_{total} is at its highest, about 3.5 and 2, for arbitrary values of ϵ'_{fer} when the free space occupies 37% (v/v) and 50% (v/v), respectively, in the coaxial holder.

In Figures 4 to 6, the reflection loss of the hexagonal ferrite absorber estimated by numerical simulation is shown by the dashed line together with the measurement value (solid line) as a function of frequency. The band profile obtained by the simulation is almost consistent with that obtained by measurement. For both the Co_2Z and $(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$ systems, the peak position (matching frequency) shifted to a higher frequency when free space was introduced into the ferrite. This is probably because the large decrease in ϵ'_{total} relative to μ'_{total} leads to an impedance mismatch, shifting the matching frequency to a higher frequency. For the grid-type absorbers with 37% (v/v) free space, both the Co_2Z and $(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$ systems had wide bandwidths: 1.8–5 GHz and 1.5–4.5 GHz (>15 dB), respectively, at a matching thickness of about 5 mm. These bandwidths are appreciably wider than those obtained for the 0%

FIG. 6. Frequency dependence of reflection loss for $(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$ -based grid-type wave absorber [free space 50% (v/v)].

(v/v) free-space systems; 1.3–2.3 GHz for the Co_2Z system and 0.9–1.5 GHz for the $(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$ system (see Table I). The matching thickness of these two systems without free space is the same (4.5 mm). The more free space, the wider the bandwidth, but the larger ferrite thickness is required. Increasing the free space led to a wider bandwidth: 1.7–9 GHz was achieved with a free space of 50% (v/v) when the thickness of the $(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$ was 7 mm (see Fig. 6).

IV. CONCLUSION

Grid-type wave absorbers composed of hexagonal ferrite showed wide bandwidths: 1.5–4.5 GHz and 1.8–5 GHz (>15 dB) for $(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$ and Co_2Z systems, respectively, when the free space occupied 37% (v/v) and the thickness of the ferrite was about 5 mm. An increase in the free space led to a wider bandwidth: 1.7–9 GHz could be achieved with a free-space of 50% (v/v) when the thickness of the $(\text{Zn}_{0.8}\text{Mn}_{0.2})_2\text{Y}$ was 7 mm.

Rapidly solidified Fe-6.5%Si alloy powders for high frequency use (abstract)

Seung Duk Choi and Choong Jin Yang

*Electromagnetic Materials Laboratory, Research Institute of Industrial Science & Technology (RIST),
P.O. Box 135, 790-600 Pohang, Korea*

Fe-(3~6.5%) Si alloy powders having a high magnetic induction (B_s) and a low core loss value for high frequency use were obtained by an extractive melt spinning as well as a centrifugal atomization technique. Sintered core rings made by the rapidly solidified Fe-6.5% Si powders exhibited the high frequency electromagnetic properties: saturated induction (B_8) of 1.23 T, coercivity (H_c) of 9.5 A/m, relative permeability (μ_a) of 6321, and core loss ($W_{10/50}$) of 1.27 W/kg from the rings of 1.1 mm thick. The saturated induction values were found to be almost identical to those of nonoriented Fe-3% Si steel sheet and 6.5% Si sheet prepared by the CVD technique. The high frequency core loss values were measured not to be changed much up to 10 kHz ($W_{1/10k}=55$ W/kg) in applied ac frequency. © 1996 American Institute of Physics. [S0021-8979(96)69208-5]

Large shielding factor obtained by a multiple-shell magnetic shield having separate magnetic shaking

I. Sasada, T. Yamamoto, and T. Yamauchi

Department of Electronics, Kyushu University 36, Fukuoka 812, Japan

Large shielding factors obtained by magnetic shaking techniques are reported. A cylindrical magnetic shield with both ends open (length=120 cm, inner diameter=52 cm) was constructed as a one-half model of an actual size. Metglas 2705M amorphous tapes of 5 cm in width and about 22 μm in thickness were wound helically on the outer surface of a tube (outer diameter=52 cm) to form a thin multiple-shell structure of five shells. The outer three shells, each made of 4 layers of tapes, were subjected to a common magnetic shaking (200 Hz). The fourth shell made of 8 layers was subjected to a different magnetic shaking (536 Hz). The innermost one was a passive shell. The shielding factor in the center of the shield measured for a transversely applied magnetic field (100 mG) showed $1/f$ -like behavior and extremely large values of 90 900 at 1 Hz and 21 000 at 10 Hz when the opening compensation was on. The shielding factor was much lower and constant at the level of 7000 at frequencies of less than 10 Hz when opening compensation was off. The residual dc magnetic field at the center was as small as 5 μG . It is shown by the experiments that a multiple-shell structure with even narrow spacings exhibits large shielding factors when a magnetic shaking technique is applied. It is also shown that the opening compensation technique is a key to building an open-structure magnetic shield with a large shielding factor. © 1996 American Institute of Physics. [S0021-8979(96)74208-X]

I. INTRODUCTION

For extremely weak and low-frequency magnetic field measurements, the use of magnetic shielding as well as the use of superconducting quantum interference device (SQUID) magnetic sensors is inevitable. Current magnetic shielding systems are based on the classical approach such as the one in Ref. 1. There is, however, a big technological gap between the SQUID sensor systems and the magnetic shielding system used today. Hence, the development of a new and effective method of magnetic shielding is a key for extremely weak magnetic field measurement techniques. The magnetic shielding system should have large shielding factor at low-frequency to attenuate ambient disturbing magnetic fields of the $1/f$ nature,^{2,3} and should be low-cost and lightweight. Furthermore, open structure is strongly recommended for easy access and for preventing claustrophobia when it is used for magnetic field measurements of the human brain in the hospital. We have been working on this issue and proposed magnetic shaking techniques applied to square BH -loop materials^{4,5} and opening compensation technique to allow an open structure.⁶

In this paper, we report on large shielding factors obtained by a cylindrical magnetic shield with a thin multiple-shell structure subjected to magnetic shaking enhancement and with a compensation system at the open ends of the shield. We emphasize the merit of the use of multiple-shell structures even with narrow spacings when the material permeability is as high as $4\text{--}6 \times 10^5$, and the effectiveness of our shield and compensation technique to get a large shielding factor on open ended shields.

II. EXPERIMENT

A cylindrical magnetic shield with both ends open (length=120 cm, inner diameter=52 cm) was constructed as

a one-half model of an actual size. Metglas 2705M amorphous tapes of 5 cm in width and about 22 μm in thickness were wound around a tube (outer diameter=52 cm) to form five separate magnetic shells as shown in Fig. 1. Shells #1–#3 carry a common toroidal shaking coil (shaking coil #1 in the figure) and shell #4 carries its own toroidal shaking coil (shaking coil #2 in the figure). The shell #5 was not subjected to magnetic shaking but used to attenuate the shaking magnetic field leaking from shells #1–#4. The total weight of the tapes used was 15 kg. Nominal diameters of the shells are 56 cm for #1, 55.3 cm for #2, 54.6 cm for #3, 52.6 cm for #4, and 52 cm for #5. Numbers of turns were 50 for shaking coils #1 and #2 and 20 for the demagnetizing coil

FIG. 1. Cross sectional view of thin multiple-structure. Spacings between shells are about 3.5 mm, unless otherwise indicated.

FIG. 2. Schematic view of opening compensation system. The system is shown only for y component of disturbing magnetic field.

on the shell #5. Excitations to the shaking coils #1 and #2 were given separately. In this case, the frequency Fs_1 of excitation #1 and the frequency Fs_2 of excitation #2 should be chosen carefully to avoid a modulation effect, in which $|2nFs_2 - mFs_1|$ Hz components, where $2nFs_2$ is even harmonics of Fs_2 and mFs_1 is harmonics of Fs_1 , appear inside shell #4, see also Ref. 7. In order to avoid $|2nFs_2 - mFs_1|$ being a low-frequency component, one can set $Fs_1 = Fs_2$, however, we chose 200 Hz for Fs_1 and 536 Hz for Fs_2 experimentally. In this combination, a 16 Hz component should appear for $n=3$ and $m=16$, but it was too small to be detected by a fluxgate magnetometer. Lower sidebands of the modulation effect become small when n and m tend to be large numbers. Figure 2 shows a schematic view of the opening compensation.⁶ Only one coil set for compensating the y-component of the disturbing magnetic field was installed for the experiments. When the sources of the disturbing magnetic fields are far from the magnetic shield, those fields can be almost the same at both ends. In this case, one can compensate magnetic disturbances at both ends by using a single magnetometer as shown.

The magnetic shield under investigation was positioned horizontally and exposed transversely to the earth's magnetic field. Shell #5 was demagnetized at the beginning of experiments with the two magnetic shaking coils excited to reduce remanent magnetization of the shell. A transverse magnetic field (100 mG) was applied to the magnetic shield by a large rectangular Helmholtz coil set⁶ and the magnetic field inside the shield was detected by a fluxgate magnetometer situated on the axis of the cylinder with a lock-in amplifier to enhance SN ratio. The distribution of the residual dc magnetic field was also measured down to 5 μ G. In these measurements, the dc magnetic field was measured more than twice at a place by reversing the direction of the magnetometer to separate offsets.

FIG. 3. Shielding factor in the center with end compensation on.

III. RESULTS AND DISCUSSION

The shielding factor (ratio of magnetic field applied to magnetic field inside) with the opening compensation on is shown in Fig. 3 for the frequencies of the transversely applied magnetic field. The shaking conditions are given in the figure. The shielding factor becomes larger toward low frequency and reaches 90 900 at 1 Hz. This is extremely high compared to the typical value of conventional magnetic shields which have normally factors of only 10–100. Incremental permeability shows a frequency dependence even at low frequencies when it is enhanced by magnetic shaking.⁵ In the present case, however, the strong frequency dependence of shielding comes not only from the frequency dependence of the permeability but also from the thin multiple-shell structure with end compensation. As shown by Thomas⁸ for an infinitely long cylindrical shield of multiple-shell structure, shielding factor is a n th order polynomial function of the relative permeability μ_r when a shield consists of n magnetic shells. In our case, the order of the polynomial function is 4 because shells #1–#4 are subjected to magnetic shaking. The permeability of shell #5 is treated as a constant equal to 2000. When the distances between the neighboring shells are small, coefficients of higher order terms become small. Therefore, when the permeability is low, higher order terms do not affect a resulting shielding factor. In other words, a thin multiple-shell structure behaves as a single shell with the same total thickness when the permeability is low. On the other hand, when the permeability is sufficiently large, higher order terms with small coefficients become substantial, so a thin multiple-shell does work to increase shielding factor.

FIG. 4. Relationship between shielding factors and relative permeability.

FIG. 5. Shielding factor in the center with end compensation off.

The shielding factors were calculated as a function of relative permeability assuming infinitely long cylindrical shields⁸ for the exact cross sectional structure and for a three shell model in which shells #1–#3 are treated as a single shell with the same total thickness and the mean diameter of the three. It is obvious that even narrow spacings (3.5 mm) between shells yield much higher shielding factor when the relative permeability is higher than 10^5 . The steep gradient of the solid line in Fig. 4 explains the strong frequency dependence in Fig. 3, that is, frequency dependence of the permeability itself is enhanced through this steep gradient. The value of shielding factor at 1 Hz, 90 900 is obtained at $\mu_r = 6.5 \times 10^5$ in Fig. 4 and the factor 21 000 at 10 Hz with $\mu_r = 4.0 \times 10^5$. These values are obtained by magnetic shaking.⁴

Figure 5 shows the shielding factors under the same shaking condition when the end compensation was off. The shielding factors were low and constant at the level of 7000 at the frequencies of less than 10 Hz due to overwhelming leaks from the openings. Figure 6 shows the flux density profile along the cylinder axis for the transversely applied magnetic field of 100 mG when the opening compensation is on. Obtaining a larger shielding factor and obtaining a wider uniform area of magnetic field is in trade-off relationship in the magnetic shield with open ends. The residual dc magnetic field profile on the same axis is shown in Fig. 7 for two cases: opening compensation on and off. When the opening compensation is on, the residual magnetic field is as small as 5 μG .

FIG. 6. Flux density profile along the cylinder axis for the transversely applied ac magnetic fields.

FIG. 7. Residual dc magnetic field profile along the cylinder axis.

One can build a magnetic shield large enough for the human body by scaling to twice the size as the one discussed with amorphous tapes weighing 120 kg. The total weight would be one tenth and the performance far better compared to conventional magnetic shields using Permalloy.

In this paper, we focused only on the shielding factor, however, leakage magnetic fields consisting of higher harmonics of the magnetic shaking field are also an important issue. To reduce these leakage fields, the shaking coils should be wound symmetrically with many turns. The use of inner shells made of magnetic materials with fairly high permeability without magnetic shaking is also effective to attenuate these shaking fields. This issue will be addressed later time.

IV. CONCLUSIONS

We demonstrated that a large shielding factor (90 900 at 1 Hz) was obtained by a cylindrical magnetic shield with magnetic shaking. We showed that a thin multiple-shell structure with even narrow spacings between the shells does increase the shielding factor when the permeability is enhanced by magnetic shaking. We also showed the effectiveness of our shield end compensation technique to get a large shielding factor on open ended shields.

The magnetomechanical effect in electrolytic iron

M. K. Devine and D. C. Jiles
Ames Laboratory, Ames, Iowa 50011

The effect of stress on the magnetization of high purity iron has been studied systematically at different locations on the M, H plane corresponding to a variety of magnetic states of the material. The results confirm earlier studies that show the sign of the derivative $dM/d\sigma$ changes at different locations on the M, H plane, and can even change as a result of a monotonic increase of stress either in compression or tension. The observed behavior can be explained on the basis of a recent theory which predicts that the irreversible changes in magnetization resulting from changes in applied stress cause the magnetization to approach the anhysteretic magnetization curve at the given applied field strength. © 1996 American Institute of Physics. [S0021-8979(96)74308-6]

INTRODUCTION

The behavior of ferromagnetic materials subjected to a time dependent applied stress has been difficult to explain theoretically. Recent work¹⁻⁴ has shown the effect can be asymmetric with respect to tensile and compressive stress, depending where on the hysteresis loop measurements were taken.

Magnetization changes occur as a result of a change in the energy of the system. The derivative of the Helmholtz free energy with respect to magnetization leads to an equation for the effective field,⁵

$$\frac{dA}{dM} = \mu_0 H + \mu_0 \alpha M + \left(\frac{3}{2} \right) \sigma \left(\frac{d\lambda}{dM} \right) \quad (1)$$

so that

$$H_{\text{eff}} = \left(\frac{1}{\mu_0} \right) \left(\frac{dA}{dM} \right) = H + \alpha M + \left(\frac{3}{2} \right) \left(\frac{\sigma}{\mu_0} \right) \left(\frac{d\lambda}{dM} \right). \quad (2)$$

Here, the effect of stress occurs in the third term. The factor $d\lambda/dM$, the dependence of magnetostriction on magnetization, determines the magnitude of the effective field under a given stress. These two factors, the stress and $d\lambda/dM$ combined, produced the magnetomechanical effect.

EXPERIMENTAL PROCEDURE

Previous research has dealt with rather complex alloys of iron, usually low to medium carbon steel. To simplify the investigation, samples of iron without carbon or other solutes were measured here. Measurements reported were made on a normalized sample of electrolytic iron (99.99% pure Fe) in the shape of a short cylindrical tensile sample, of dimensions 95 mm length, and 12 mm gauge diameter. A flux coil, strain gauge and Hall-element sensor were attached. The sample was magnetized using a solenoid. Four measurements were taken at constant field strengths, with magnetizations along the upper branch of the hysteresis loop (i.e., decreasing from saturation magnetization): these included measurements at remanence, positive and negative saturation as shown in Fig. 1. The sample was cycled through two complete hysteresis loops before setting the magnetic field H at the desired level prior to measurement. Tension and compression were applied via a mechanical tensile tester and the stress axis was co-axial with the magnetization. Stress was applied in a series of

stress/release cycles, with the amplitude increasing slightly with each cycle. The variation of flux density with strain was then recorded.

RESULTS

The magnetomechanical effect measured near saturation induction is shown in Fig. 2. At this location the derivative $d\lambda/dM$ was negative. Under tensile stresses the magnetic induction B decreased while under compression it increased. There was a small amount of irreversibility after each cycle amounting to less than 0.5×10^{-4} T per cycle.

The magnetomechanical response at a magnetic induction of 1.64 T ($H = 6600$ A/m) is shown in Fig. 3. At this location the derivative $d\lambda/dM$ was positive. Tension produced a positive change in magnetic induction while compression induced a decrease. There was greater irreversibility present after compression than after tension. Also, a significant amount of the decrease in induction occurred just after the stress for a given cycle exceeded the maximum of the previous cycle. The incremental amount of irreversibility after each cycle decreased as the number of cycles increased.

The behavior at remanence ($B = 0.34$ T, $H = 0$) is shown in Fig. 4. Here there was a decrease in induction, regardless

FIG. 1. Hysteretic (line) and anhysteretic curves (points) for the iron specimen, zero stress.

FIG. 2. Magnetomechanical effect near positive saturation induction (point A in Fig. 1).

of whether the applied stress was positive or negative. Under tensile stress there was less change than under compressive stress. The behavior under compression was similar to that seen in Fig. 3, that is much of the induction change occurred after the maximum stress of the previous cycle has been exceeded. In addition, the direction of the induction change upon application (but not release) of the stress changed direction. During the first two stress/release cycles the induction increased with stress, but afterwards the induction decreased with stress.

Figure 5 shows the behavior at $H = -6600$ A/m, and an induction of -1.55 T. The behavior here was similar to those seen in Fig. 3 except the sign of the stress response was reversed. Tension produced a decrease in induction while compression produced an increase, and there was significant hysteresis on the tensile side.

FIG. 3. Magnetomechanical effect at applied magnetic field $H = +1/2 H_{\max}$ (point B in Fig. 1).

FIG. 4. Magnetomechanical effect at positive remanence (point C in Fig. 1).

DISCUSSION

The observed magnetomechanical effect near saturation induction (Fig. 2) was a reversible response to stress. Near saturation, the derivative of magnetostriction was negative⁶ so the change in magnetization was negative for tensile stresses and positive for compressive stresses. Since domain magnetization rotation is a reversible process, the curves in Fig. 2 are similarly reversible. The effective field H_{σ} at saturation was calculated to be -192 A/m at maximum tensile stress and $+312$ A/m at maximum compressive stress. These fields are of the magnitude required to produce the small observed change in induction.

Far from saturation, different magnetization mechanisms dominated the process. After domain rotation, the first mechanism to be activated upon decrease from saturation is

FIG. 5. Magnetomechanical effect at applied magnetic field $H = -1/2 H_{\max}$ (point D in Fig. 1).

domain wall translation. At $H=6600$ A/m, reverse domains were created and grew (via wall movement), which reduced the magnetization. Since the magnetostriction is positive in this region,⁶ the effective magnetic field due to the stress tends to increase the magnetization. Thus the applied field (from the solenoid) H_{app} and the effective magnetic field (from the stress) H_{σ} oppose each other in the tensile regime and reinforce each other in the compressive regime. At this point, the effective field H_{σ} was calculated to be 480 A/m from the tensile stress and -780 A/m from the compressive stress.

At remanence there is no applied field but the induction decreased with stress both in the tensile and compressive regime. This is because at this point the magnetization is above the anhysteretic and stress cycling will tend to reduce the total energy by decreasing its magnetization. The tendency for larger changes in magnetization to occur in the compressive regime is because compressive stress favors the formation of domains orientated at 90° to the applied stress axis (usually in the form of closure domains).² Since more

90° domains are formed in compression than in tension, the magnetization decrease more under compression.

CONCLUSIONS

The magnetomechanical effect is known to produce apparently complicated behavior in iron. The response of the material has been shown to be asymmetrical, contrary to earlier theories. The behavior of the magnetization as a function of stress depends on which magnetization mechanism is dominant at a particular point on the hysteresis loop and also on the sign of the derivative ($d\lambda/dM$). The observed results have been explained in terms of a recent theory of the magnetomechanical effect.⁷

Effect of cutting techniques on local magnetic characteristics of SIFE (abstract)

D. A. Philips, L. R. Dupre, K. Eloot, and J. A. Melkebeek

Laboratory for Electrical Machines and Power Electronics, Department of Electrical Power Engineering, University of Gent, Belgium

In this article the effect of cutting techniques on the local magnetic characterization of nonoriented motor lamination iron is presented. Starting from the same material (0.3% Si, 0.3% Al, finally annealed condition), rings have been cut using three different techniques: spark erosion, laser cutting, and punching. First a classical¹ measurement has been performed on stacks of ten identical rings, using a measurement winding applied uniformly along the circumference of the ring. In this way, the *average BH* loops under quasistatic conditions have been obtained, and are used as a *reference* further on. It is found that the cutting techniques have a considerable impact on these average magnetic characteristics. In a second step, local measurement windings have been wound on single rings. The quasistatic *BH* loops have then been measured as a function of the position along the circumference of the ring, with *B* still the average induction over the entire magnetic cross section. A systematic fluctuation of typically 5% around the reference loop has been observed for all three materials, which cannot be attributed to measurement errors. In a third step, quasistatic *local BH*-loops have been measured at different radial positions. A dedicated measurement technique² has been used, allowing the measurement of the local flux between two points 1 mm apart. No variation of the *BH* loops with the radial position has been observed in case of the material cut using spark erosion. This result is in agreement with the very low mechanical impact of the cutting technique. In case of the material cut with a laser, a considerable variation of the *BH*-loops with the radial position has been observed. This proves that the heat affected zone extends several mm inside the material. For the punched material again no variation with the radial position could be observed. This shows that the impact of the punching is confined to a region <1 mm wide, close to the edge. © 1996 American Institute of Physics. [S0021-8979(96)69308-1]

The soft magnetic properties of stripes fabricated using laser ablation of multilayer thin films

Craig A. Grimes and Janet K. Lumpp

Department of Electrical Engineering, The University of Kentucky, Lexington, Kentucky 40506

We examine the low frequency BH loop and complex permeability spectra of multilayer permalloy films laser processed to define samples consisting of stripes parallel to the as-deposited hard axis. We begin by examining different laser energy densities for groove definition in films of different thickness. We observe that for well coupled multilayer films with thin, 15 nm, spacer layers the demagnetizing field, which is a function of groove depth, is able to reorient the easy and hard axes from the initial orientation. As the groove becomes more clearly defined the hard axis permeability increases, while the easy axis permeability decreases. The role of stripe width and ambient processing atmosphere are also investigated. © 1996 American Institute of Physics. [S0021-8979(96)74408-5]

I. INTRODUCTION

Magnetic structures such as sensors^{1,2} and identification markers^{3,4} are typically fabricated using photolithographic techniques, in conjunction with etching or ion milling, to define the required geometries from magnetically soft multilayer thin films.⁵ The magnetic properties of such devices are process dependent. To see if laser processing could offer a practical alternative to conventional photolithographic techniques we have investigated the use of a KrF excimer laser, with a 100- μm diam spot size and 248 nm wavelength, to define stripe patterns on magnetically soft multilayer thin films by ablation.

The multilayer films consist of four, eight, or twelve 80 nm $\text{Ni}_{81}\text{Fe}_{19}$ magnetic layers separated by either 15 or 45 nm silicon nitride spacers layers. The original samples were 16 mm squares; the laser beam was rastered across the samples parallel to the hard axis to define stripes separated by the 100- μm -wide laser ablated channel.

Figure 1 shows the experimental setup used for defining stripe geometries upon homogeneous multilayer magnetic thin films by ablation. The setup includes a MPB PSX-100 excimer laser, beam delivery optics, and a vacuum chamber. Excimer lasers do not operate continuously, but deliver pulses of high optical power. The sample holder is in the vacuum chamber which is mounted on a motorized translation stage. Vacuum processing was performed at a base pressure of approximately 10^{-3} Torr. The laser beam was incident normal to the basal plane of the sample. A 100- μm -diam spot size was used throughout this work, with a constant scan speed of 0.635 mm/s. The pulse repetition rate was 25 Hz, producing a constant spacing between pulses of 25.4 μm . Incident energy densities were 3.2, 8, and 18 J/cm^2 ; the laser pulse was 2.5 ns for power densities of, respectively, 1.3, 3.2, and 7.4 GW/cm^2 .

The magnetic thin films examined in this study were fabricated using dc magnetron sputtering. The films were deposited onto 52- μm -thick PET (polyethylene terephthalate).⁶ Prior to deposition the substrate was cleaned by sputter etching the substrate web in oxygen at a power level of 3 W/cm^2 for 6 s.⁶ Background pressure in the sputtering chamber was 1.8 mTorr, the sputtering gas was argon. The

films consisted of 80 nm $\text{Ni}_{81}\text{Fe}_{19}$ magnetic layers and silicon nitride (Si_3N_4) spacer layers that were either 15 nm or 45 nm thick. A 100 nm Si_3N_4 undercoat separated the substrate and first permalloy layer.⁷ The silicon nitride layers were deposited by reactive sputtering from a silicon target in a nitrogen-rich environment.

The samples were cut into 16 mm squares, with the magnetic easy axis (EA) and hard axis (HA) perpendicular to each other along one axis of the square. All stripes were defined parallel to the HA. The lines were scanned 0.5, 1.0, or 2.0 mm center to center, resulting in stripes 0.4 0.9, and 1.9 mm wide with 0.1 mm separating grooves.

The low frequency BH loops (10 Hz), anisotropy field and coercive force were measured using a SHB BH -Looper. The complex permeability spectra was measured from 5 to 100 MHz using a thin film permeameter.⁸

II. RESULTS

Six different multilayer films were laser processed in air at the three different energy densities. Table I summarizes the degree to which the laser ablated grooves were defined.

Figure 2 shows the change in the 10 Hz BH loop of the film in response to laser rastering 0.9-mm-wide stripes across

FIG. 1. Experimental setup including laser system, translation stages, and vacuum chamber.

the sample, parallel to the HA, at the three energy densities. The original films were nearly isotropic, with a measured anisotropy field of approximately 1.4 Oe. Figure 2(a) shows the *BH* loop of the film laser rastered at 3.2 J/cm², the general shape of the *BH* loop is essentially unchanged from the as-deposited state, however, the EA and HA have switched directions. Figure 2(b), laser rastered at 8 J/cm², shows clearly discernible EA and HA, which are reversed from the as deposited state. Figure 2(c) laser rastered at 18 J/cm², has the *BH* loop characteristic of a uniaxial film. The switching of the EA and HA directions from the as deposited orientation can be explained in terms of the demagnetizing field.⁹ The stripe is 0.9 mm wide and 1.125 μm thick for a demagnetizing factor of approximately 1.2×10^{-3} . Taking $4\pi Ms$ of the permalloy layer to be 10 400 G, the average $4\pi Ms$ value of the multilayer stack is ≈8875 G. The demagnetizing field of the stripe, which acts to orient the magnetization vector along the length of the stripe (the as-deposited HA), is simply the product of the demagnetizing factor and average $4\pi Ms$ value, approximately 10 Oe. With reference to Fig. 2, this demagnetizing field plays the role of the anisotropy field, which can be determined by extrapolation of the initial, HA linear magnetization curve. The measured *Hk* is 7 Oe, which combined with *Hk* of the as-deposited film indicates a change in the anisotropy field of 8.4 Oe, a value comparable to that calculated for the demagnetizing field.

Figures 3(a) and 3(b) show, respectively, the HA and EA 5–100 MHz complex permeability spectra of the same films measured in Fig. 2. The permeability is measured after application of a saturating dc magnetic field oriented perpendicular to the high frequency measurement field.⁸ The HA permeability increases and the EA permeability decreases as the magnetization vector becomes increasingly oriented,

FIG. 2. The 10 Hz *BH* loops of multilayer films consisting of twelve 80 nm Ni₈₁Fe₁₉ layers and eleven 15 nm Si₃N₄ spacer layers laser rastered to define 0.9-mm-wide stripes, separated 0.1 mm at energy densities of (a) 3.2 J/cm² for partial line definition, (b) 8 J/cm² for substantial line definition, and (c) 18 J/cm² for complete line definition. X-scale is 5 Oe/div. Y-scale is arbitrary units.

which is caused by the geometry becoming more clearly defined through use of higher laser energy densities. Note the scale of Fig. 3 does not take into account the thickness of the spacer layers, or the reduction in material that has been ablated to define the stripes. Figure 4 shows a typical HA complex permeability spectra plot of the as-deposited film; the as-deposited EA trace is similar in shape, but reduced in magnitude by 65% from the HA. As expected, since perme-

(a) Frequency (MHz)

(b) Frequency (MHz)

FIG. 3. (a) The hard axis complex permeability spectra of same films shown in Fig. 2: (a) μ' high energy raster, (b) μ' medium energy, (c) μ' low energy, (d) μ'' high energy, (e) μ'' medium energy, (f) μ'' low energy. (b) Corresponding easy axis of (a).

ability magnitude is inversely related to the anisotropy field, the laser processed samples show a dramatic reduction in permeability from the relatively isotropic as-deposited state.

The response of the 45 nm spacer layer films to laser processing is more complicated. In contrast to the 15 nm spacer layer films, the as-deposited 45 nm spacer layer films were fairly well oriented, with an anisotropy field of approximately 5.5 Oe, and, as seen by the BH loop, the different magnetic layers tend to act individually. The response of these thicker films to laser processing is still being studied.

The effect of different stripe widths was investigated by defining 1.9, 0.9, and 0.4 mm stripes, separated by 100 μm grooves, by laser rastering at 18 J/cm². Generally speaking, for all films smaller stripe widths resulted in higher coercivi-

FIG. 4. As deposited, hard axis complex permeability spectra of films laser processed for Fig. 3.

ties; for the 15 nm spacer layer films smaller stripe widths resulted in larger anisotropy field values, while for the 45 nm spacer layer films the anisotropy field stayed generally constant with stripe width. Table II summarizes data obtained on multilayer films consisting of four magnetic layers with either 45 nm or 15 nm spacer layers: $|\mu|$ denotes the 5 MHz permeability magnitude.

The role of ambient atmosphere was investigated by comparing the magnetic properties of the same six different multilayer films rastered in vacuum at 18 J/cm² to define 0.9 mm stripes. Generally speaking, there was little difference in the measured magnetic properties between samples rastered in air or vacuum, although optical inspection showed them to be quite different in appearance. The material laser ablated in air redeposited on the sample in some kind of silicon nitride/permalloy mixture; it appeared that the redeposition plume was approximately 0.5 mm in width. The samples laser processed in vacuum were clean with no sign of redeposition.

Magnetic garnet film epitaxy on nonsingular faces (abstract)

S. S. Gorelik, L. M. Letyuk, and A. T. Morchenko

Moscow State Institute of Steel and Alloys, Leninsky Prospect 4, Moscow, 117936 Russia

The single crystal films of magnetic garnets are widely used in various microelectronics devices. The yttrium-iron and bismuth-gallium-substituted magnetic garnet films were grown by liquid phase epitaxy from supercooled solutions on the basis $\text{PbO} + \text{B}_2\text{O}_3$. As substrates for films the gadolinium-gallium garnet wafers crystallographically oriented in the range from (111)- to (110)-directions are used. In experiments such growth process parameters as supercooling temperature and angular velocity of substrate rotation were varied too. The parameters to be examined were thickness, growth rate, crystallographic, magnetic, and magneto-optical characteristics of the as-grown films. To analyze the growth process kinetics it was developed the model, including the terms (supersaturation $C_L - C_E$) of the first and second orders for description of surface crystallization reaction. The following expression was derived for epitaxial growth rate:

$$f = \frac{D}{\rho\delta} \left[(C_L - C_E) + \frac{k_1\delta + D}{2k_2\delta} - \frac{\sqrt{(k_1\delta + D)^2 + 4k_2\delta D(C_L - C_E)}}{2k_2\delta} \right],$$

where D is diffusion coefficient, δ is diffusion boundary layer thickness on the solid-liquid interface, ρ is film density, C_L is concentration of garnet phase in the melted solution, C_E is equilibrium concentration, k_m is surface reaction constant (kinetic coefficient) of order m in

$$D \frac{\partial C}{\partial x}(0, t) = k_m [C(0, t) - C_E]^m.$$

A selected parameters are given for $(\text{YBi})_3(\text{FeGa})_5\text{O}_{12}$ films grown under the same conditions:

The effects of average grain size on the magnetic properties and corrosion resistance of NdFeB sintered magnets

D. W. Scott, B. M. Ma, Y. L. Liang, and C. O. Bounds

Rhône-Poulenc, Rare Earths and Gallium, CN 7500, Cranbury, New Jersey 08512

Magnets with a nominal composition of $\text{Nd}_{14.5}\text{Fe}_{79.5}\text{B}_6$ have been prepared by the conventional powder metallurgy technique. Precursor alloy powders with average particle sizes of 2.5, 3.0, 3.5, and 4.2 μm were included in this study. Average particle size and oxygen content were effectively manipulated to control the average grain size in the sintered magnets. Typically, for NdFeB sintered magnets, the corrosion resistance of these magnets was improved with increasing oxygen content. The corrosion resistance of magnets varied significantly with the average particle size of precursor alloy powders. For a fixed oxygen content, magnets made from powders of larger sizes exhibited a higher weight loss (a poor corrosion resistance) when compared to those made from smaller alloy powders. However, the H_{ci} of magnets made from 2.5, 3.0, and 3.5 μm precursor alloy powders was found to decrease drastically with increasing oxygen content while magnets made from the 4.2 μm powder was found to remain relatively constant with increasing oxygen content. To optimize magnetic performance, one needs to compromise the corrosion resistance and the H_{ci} obtained by balancing the average particle size of the precursor alloy powder for magnet fabrication, as well as the oxygen content and the average grain size in the finished magnet. © 1996 American Institute of Physics. [S0021-8979(96)31508-9]

INTRODUCTION

The average grain size of finished magnets has been found to be a determining factor for the B_r , H_{ci} , and BH_{max} obtained for NdFeB magnets prepared by the powder metallurgy (P/M) and sintering route.¹⁻³ Using the P/M process, oxygen pick-up has always been a concern for magnet manufacturing. Increasing oxygen content to a certain limit has been found to improve the bulk corrosion resistance and the magnetic properties, namely, B_r , H_{ci} , and BH_{max} of the magnets obtained.^{4,5} This raised an interesting idea for producing sintered magnets with both good bulk corrosion resistance and a high H_{ci} and BH_{max} . By balancing the milled powder particle size (or the surface area obtained), powder handling, oxygen pick-up, and sintering conditions: one can actually manipulate the average grain size and the oxygen content in the finished magnets.

In this article, we discuss two different means of controlling the average grain size in sintered NdFeB magnets by (1) varying the average particle size of precursor alloy powder and (2) controlling the oxygen content in finished magnets. It is our intention to relate the B_r , H_{ci} , BH_{max} , and H_k of finished magnets to the average particle size of precursor alloy powders. The relationship of the bulk corrosion rate of the finished magnets to the average grain size and oxygen content will also be discussed.

EXPERIMENT

Magnets included in this study were prepared from a conventionally cast alloy with a nominal composition of $\text{Nd}_{14.5}\text{Fe}_{79.5}\text{B}_6$ using classical powder metallurgy techniques. Four batches of powders with average particle sizes of 2.5, 3.0, 3.5, and 4.2 μm were then prepared by attrition milling. To study the effects of oxygen content on both the magnetic

performance and the corrosion resistance, milled powders were deliberately oxidized in a controlled manner. Other than the oxidation step, the magnet fabrications and corrosion testing were identical to regular magnets as reported in previous work.³

RESULTS AND DISCUSSION

Table I presents the relationships of the bulk corrosion rate (the weight loss) and the magnetic properties of finished magnets to the average particle size of precursor alloy powders, the average grain size, and the oxygen content in the finished magnets. Magnets made from powders of 2.5 μm powders typically exhibit a higher oxygen content than those made from larger powders exposed to the same amount of air. When processed under the low oxygen condition (i.e., without introducing any excessive air for controlled oxidation), the oxygen contents in finished magnets range from 0.12 to 0.14 wt % for all magnets regardless of the average particle size of powders. When a slight amount of oxygen (150 ml) was introduced, the oxygen content in finished magnets increased sharply from a 0.13 wt % to about 0.47, 0.40, 0.37, and 0.41 wt % for magnets made from precursor alloy powders with the average particle size of 2.5, 3.0, 3.5, and 4.2 μm , respectively. This rapid increase in oxygen content suggests that the precursor alloy powders included in this study exhibit a very high oxygen (or air) affinity.

Shown in Fig. 1 is the relationship between oxygen content of finished magnets and the amount of air injected for controlled oxidation and the average particle size of precursor alloy powders. As mentioned earlier, the oxygen content in finished magnets increased exponentially at low amounts of air injection then become relatively flat when the amount of injected air was increased to more than 300 ml. Because of the smaller particle size and, presumably, the high surface

area and chemical potential, magnets made from precursor alloy powder of 2.5 μ m in size yielded an oxygen content of more than 1.5 wt % when 300 ml of air was injected for controlled oxidation. This value is much higher than magnets made from 3.0, 3.5, and 4.2 μ m powders when exposed to the same amount of air. These trends suggest that the average particle size of the precursor alloy powder is a very important factor for magnet processing. Thus, the desired average particle size of precursor alloy powder must be balanced with the oxygen pick-up occurring during processing in order to optimize desired properties.

FIG. 1. Relationship of oxygen content in finished magnets to the average particle size of precursor alloy powder and the amount of air injection used for conduction control oxidation.

For a fixed precursor alloy powder, the weight loss of magnets obtained decreased with increasing oxygen content in finished magnets. However, there is an important phenomenon which should be addressed concerning the relationship of the bulk weight loss to the oxygen content of finished magnets. Shown in Fig. 2 is the relationship of weight loss of finished magnets with a 0.1 and 0.4 wt % oxygen content to the average particle size of precursor alloy powders. For a fixed oxygen content, the weight loss increased with increasing size of precursor alloy powder. When the oxygen content of finished magnets was increased from 0.1 to 0.4 wt %, a lower weight loss (i.e., a better corrosion resistance) was obtained as anticipated. This phenomenon may be explained

FIG. 2. Relationship of weight loss to the average particle size of precursor alloy powder and the oxygen content in finished magnets.

FIG. 3. Optical micrograph of magnets produced from precursor alloy powders with average particle size of (a) 2.5, (b) 3.0, (c) 3.5, and (d) 4.2 μm (FSSS) under low oxygen process. The oxygen content of these magnets were all maintained at about 0.13–0.14 wt %. The average grain size of these magnets are 7.1, 7.5, 8.8, and 9.0 μm , respectively.

by the fact that the Nd-rich phase is more evenly distributed in magnets made from precursor alloy powders of smaller sizes; this issue requires further investigation.

Shown in Figs. 3(a)–3(d) are optical micrographs of magnets made from precursor alloy powders with average particle sizes of 2.5, 3.0, 3.5, and 4.2 μm , respectively, at the lowest oxygen content (0.13–0.14 wt %). As with any P/M process, grain growth occurs during sintering resulting in average grain sizes in the sintered magnets of 7.1, 7.5, 8.8, and 9.0 μm , respectively. Although the average particle size of powder measured by the FSSS cannot be directly translated to the average grain size of finished magnets measured by an image analyzer, it is known that grain growth is more rapid in magnets made from powder of 2.5 μm when compared to those made from 3.5 or 4.2 μm . Besides the difference in average grain sizes of finished magnets, the size of the Nd-rich phase⁶ in a magnet made from the 4.2 μm powder appeared to be larger than that made from 2.5 μm . The large size of Nd-rich grain boundary phase may be one cause of the high weight loss of magnets made from powders of large average particle size.

Shown in Figs. 4(a)–4(d) are optical micrographs of magnets made from precursor alloy powder with an average particle size of 3.0 μm with oxygen contents of 0.12, 0.40, 0.53, and 0.65 wt %, respectively. The average grain sizes of these magnets (7.5, 7.1, 6.9, and 6.2, respectively) decreased slightly with increasing oxygen content in finished magnets suggesting that the oxygen (or oxides formed) may act as a grain growth inhibitor during sintering. The size of the Nd-rich grain boundary phase also appeared to be larger and more agglomerated in magnets of low oxygen content (0.12 wt %) than those of higher oxygen contents (0.40, 0.53, and 0.65 wt %). This change in the size and the distribution of the Nd-rich grain boundary phase may contribute to the improvement in weight loss of magnets with oxygen content of more than 0.4 wt %.

FIG. 4. Optical micrographs of magnets made from precursor alloy powder with average particle size of 3.0 μm with oxygen content of (a) 0.12, (b) 0.40, (c) 0.53, and (d) 0.65 wt % in finished magnets.

Despite the improvement in corrosion resistance (lower weight loss), the H_{ci} of magnets made from 3.0 μm powder decreased from 13.4 to 9.0 kOe (listed in Table I) when the oxygen content was increased from 0.12 to 0.65 wt %. The opposing trends of corrosion resistance and H_{ci} with increasing oxygen content raises an interesting issue: one may need to compromise low weight loss (good corrosion resistance) with high H_{ci} by adjusting the oxygen content in magnets. The decrease of H_{ci} with increasing oxygen content suggests that the Nd-grain boundary phase may have been over oxidized and transforms into nucleation centers during magnetization reversal. The decrease in H_{ci} with increased oxygen content becomes more pronounced when magnets were prepared from the 2.5 μm precursor alloy powder. A similar trend (but less severe) can also be observed on magnets made from 3.5 μm precursor alloy powder. For magnets made from the 4.2 μm precursor alloy powder, this situation is reversed: a slight increase in H_{ci} can be observed when the oxygen content was increased from 0.13 to 0.40 wt %. This opposite trend may be attributed to the fact that the large size of the Nd-rich grain boundary phase is only partially oxidized and still serves as grain insulators for enhancing the H_{ci} .² Unlike H_{ci} , both B_r and BH_{max} seem to be less sensitive to the increasing oxygen content. The variation of H_k with the size of precursor alloy powder or the oxygen content appeared to be very similar to that of H_{ci} .

Unusual magnetic behavior in Nd-Fe-B alloy powder compacts

H. Wan,^{a)} F. T. Parker, F. F. Putris, and A. E. Berkowitz

Center for Magnetic Recording Research, University of California-San Diego, La Jolla, California 92093-0401

We report an unusual magnetic behavior in powders prepared by spark-eroding (in liquid Ar) alloy electrodes containing approximately equal weights of Fe and Nd₂Fe₁₄B in an effort to prepare composite permanent magnets. Magnetization exhibits reproducible thermal hysteresis, peaking in all applied fields near 520 °C when warming, but increasing monotonically when cooling to room temperature from 700 °C and above. Mössbauer spectroscopy was used to show that the behavior is due to the metastability of Fe_{1-x}O produced in the powders by partial oxidation in Ar gas flow. This compound, paramagnetic at room temperature, decomposes only slowly below 570 °C into ferromagnetic Fe and ferrimagnetic Fe₃O₄. The reverse reaction occurs readily at higher temperatures. © 1996 American Institute of Physics. [S0021-8979(96)31608-5]

I. INTRODUCTION

Materials based on the intermediate compound Nd₂Fe₁₄B offer some of the best permanent magnet properties available.¹ Recently, methods to improve the permanent magnet characteristics have been devised.² In the exchange-spring concept, small particles of relatively high magnetization and low magnetocrystalline anisotropy are exchange coupled to small particles of lower magnetization and large magnetocrystalline anisotropy. Particles can be no larger than a few hundred angstroms. One obtains intermediate properties, hopefully with a larger magnetic energy product. Some improvement may be found for randomly aligned particles, with more improvement for aligned particles.³ Several attempts have made to realize these exchange couples, with the system Fe-Nd₂Fe₁₄B as a typical example. The usual process consists of rapid quenching of the melt to achieve a nearly uniform stoichiometry, often in amorphous structural form, followed by careful annealing to achieve the necessary small grain size. We have previously⁴ described preparation by spark erosion of particles of the initial homogeneous alloy mixture of Fe-Nd₂Fe₁₄B. In this work, we describe an unusual magnetization thermal hysteresis obtained while annealing spark-eroded particles. This is shown to result from two factors: the ease of oxidation of the elements Nd and B, and the metastability of the compound Fe_{1-x}O which is formed due to partial oxidation of the Fe.

II. EXPERIMENTAL DETAILS

Nd₂Fe₁₄B and Fe were chosen as the high anisotropy and high magnetization phases, respectively. Elements were arc melted to make electrodes. These contained 47 wt % Fe and 53 wt % Nd₂Fe₁₄B. Particles of various sizes were produced by spark erosion in liquid Ar, and stored under pentane. Size-cut fine particles (less than 5 μm diam) were obtained by sedimentation in pentane, then dried in Ar and pressed in Ar at about 80 kpsi. X-ray diffraction on the pellets showed an amorphous structure.

Two experimental techniques were primarily used for measurement. Magnetization (*M*) was measured on a vibrat-

ing sample magnetometer (VSM) in applied field (*H*) to 24 kOe and at temperatures of 296 K and above. Transmission Mössbauer spectroscopy (TMS) measurements were obtained between 79 and 296 K. Velocity calibration and isomer shift reference were obtained with Fe metal at 296 K.

Samples for VSM measurement and TMS were prepared and treated in similar ways. Both were subject to an initial 700 °C crystallization anneal in flowing Ar of 99.99% purity for 20 min. VSM measurements lasted several hours with the sample in a stainless steel furnace in flowing Ar. Several pellets were examined by VSM measurement. The single pellet used in TMS was annealed in flowing Ar in a quartz tube furnace. The Mössbauer pellet had to be somewhat thinner than the VSM pellets (~20 vs ~60 μm).

III. RESULTS AND DISCUSSION

Magnetization versus temperature (*T*) measurements for freshly pressed, unannealed powder showed a broad magnetic transition near 180 °C, characteristic of amorphous Nd-Fe-B. After the initial crystallization anneal, multiple temperature sweeps of *M* vs *T* were obtained. Some ex-

FIG. 1. Magnetization of spark-eroded Nd-Fe-B alloy powder compact vs temperature. The applied fields are shown on the curves. Arrows denote heating and cooling. A complete thermal loop lasted several hours. The sample had been previously annealed at 700 °C (20 min).

^{a)}Current address: Solid State Electronics Center, Honeywell, Inc., Plymouth, MN 55441.

FIG. 2. Magnetization of spark-eroded Nd-Fe-B alloy powder compact vs temperature. The procedure was similar to that shown in Fig. 1, but heating was interrupted at about 465 °C (10 min holding time) and the sample cooled to near room temperature.

amples are shown in Figs. 1 and 2. A large thermal hysteresis is seen in the full-temperature sweep, in both large and small H . Several pellets exhibited similar behavior. On increasing temperature from room temperature (RT), the magnetization shows relatively little change at first, but then increases sharply, reaching a maximum near $T=520$ °C. M then decreases rapidly, and levels off until the Curie temperature (T_C) of α -Fe metal at 770 °C. On then decreasing T , one again finds the α -Fe T_C , but the magnetization then shows a slow monotonic increase to RT. The magnetization at RT is about the same as the initial value. Subsequent thermal loops show similar behavior. If the sample is heated from RT to near 465 °C and then cooled, the larger M is retained at RT (Fig. 2). Subsequent warming retraces the cooling curve, with M dropping sharply above 560 °C as seen in the previous thermal loop (Fig. 1). There is no indication of any $\text{Nd}_2\text{Fe}_{14}\text{B}$ ($T_C=312$ °C).¹ The M vs H curves obtained at various points on the thermal loop show normal ferromagnetic behavior. A sample warmed from RT to 700 °C (the initial crystallization temperature) and then cooled exhibits no peak in M while cooling, with magnetization behavior similar to samples cooled from above the T_C of α -Fe, but with a slightly larger M at all temperatures. The thermal hysteresis seen in all samples seems incompatible with any possible explanation based on purely thermomagnetic arguments.

Mössbauer spectroscopy was used to determine the iron-containing compounds at three positions on the thermal hysteresis curve (Fig. 3). The pellet was first measured after the initial crystallization anneal at 700 °C, which yielded a relatively low magnetization on a small portion of the pellet. This preparation is denoted LM1. The pellet was then heated at 400 °C for 10 min, yielding a larger M , and the preparation is denoted as HM. The pellet was then heated at 850 °C for 10 min, the result denoted as LM2. At this point, the pellet was somewhat reduced in area and in several large pieces. The Mössbauer spectral area is thus reduced relative to the area obtained in the two previous measurements. Warming to and cooling from each treatment temperature

FIG. 3. Mössbauer data obtained for spark-eroded Nd-Fe-B alloy powder compact at 296 K. The measurement denoted as LM1 was obtained after the initial 700 °C (20 min) crystallization anneal, HM after subsequent 400 °C (10 min) anneal, and LM2 after subsequent 850 °C (10 min) anneal. The lines denote least-squares fits.

took only a few minutes, in contrast to the much longer times at elevated temperatures in the VSM furnace.

The Mössbauer spectrum of LM1 can be identified as a combination of subspectra from magnetic α -Fe and paramagnetic Fe_{1-x}O (Table I). The former exhibits a characteristic sextet with a magnetic hyperfine field of 330 kOe and a zero isomer shift. Fe_{1-x}O exhibits a broad quadrupole-split doublet with a large, positive isomer shift characteristic of Fe^{2+} (Table I). There is no evidence of $\text{Nd}_2\text{Fe}_{14}\text{B}$ in the spectrum. By determining the upper limit on the amount of the relatively low-field (287 kOe) $16k_1$ subspectrum of $\text{Nd}_2\text{Fe}_{14}\text{B}$,⁵ one finds less than 0.2% of the Fe in $\text{Nd}_2\text{Fe}_{14}\text{B}$, compared to the expected 45%. Similar oxidation characteristics have been seen⁶ on the surface of bulk $\text{Nd}_2\text{Fe}_{14}\text{B}$, which was annealed for 1 h at 600 °C in a vacuum with O_2 - H_2O partial

TABLE I. Mössbauer parameters for each preparation at 296 K. The first section shows the Fe metal atom fraction for each phase, separated into magnetic and nonmagnetic subsections. Statistical errors are shown in parentheses. The next section shows the fraction of Fe in all of the phases listed in the first section. The final section tabulates the average quadrupole splitting (ΔE) and isomer shift (IS) for Fe_{1-x}O .

Metal atom %	LM1	HM	LM2
Magnetic			
% Fe metal	57(1)	55(1)	44(1)
% Fe_3O_4	<1	19(1)	<1
Nonmagnetic			
% Fe^{2+}	39(2)	24(1)	36(3)
% Fe^{3+}	4(1)	2(1)	19(3)
Fe/(Fe+O)	0.69	0.66	0.62
Fe^{2+}			
$\langle \Delta E \rangle$ (mm/s)	0.69(1)	0.26(1)	0.70(1)
(IS) (mm/s)	0.93(1)	1.07(1)	0.92(1)

pressures about 5 orders of magnitude lower than for our treatment. Pure Fe metal was found on the surface, the much more electropositive Nd and B preferentially oxidizing into nonmagnetic (at RT) elemental oxides. Oxidation has apparently occurred in our samples due to the water vapor content of the Ar gas used in preparation and VSM measurements.

Several changes are seen in the Mössbauer spectrum of the HM preparation. Most notable is the presence of spinel Fe_3O_4 , which can be recognized by the two peaks at the most negative velocity, characteristic of the two subspectra hyperfine field pattern in cubic magnetically ordered Fe_3O_4 . The relative subspectral areas, magnetic hyperfine fields of 483 and 450 kOe, and isomer shifts, 0.28 and 0.63 mm/s, respectively, are consistent with Fe_3O_4 .⁷ The fractional amount of Fe_{1-x}O has decreased from LM1, and the quadrupole splitting decreased, as expected⁸ for annealed Fe_{1-x}O . The fraction of Fe metal has stayed about the same, even though the

oxygen-to-iron ratio has increased from LM1 (Table I). Finally, preparation LM2 shows a spectrum similar to that for LM1, with no Fe_3O_4 , but with a small fraction of quadrupole-split nonmagnetic Fe^{3+} . The fraction of Fe metal has decreased sharply from HM, and the amount of Fe_{1-x}O increased. Mössbauer data obtained at lower temperatures (not shown) exhibited the Fe_{1-x}O Néel transition near 200 K, as expected.⁸

The unusual cyclic magnetic behavior is therefore due to the metastable nature of Fe_{1-x}O . This material is stable only above 570 °C, but is metastable below about 200 °C.⁸ At intermediate temperatures, it decomposes approximately as $4\text{FeO} \rightarrow \text{Fe} + \text{Fe}_3\text{O}_4$. Both decomposition products exhibit significant magnetization in the decomposition temperature range, and provide the surge in magnetization as T is raised above 400 °C. Above this T , the Curie point of Fe_3O_4 (585 °C) and reformation of Fe_{1-x}O cause a rapid decrease in M . The T_C of $\alpha\text{-Fe}$ provides the highest- T magnetic transition. On cooling, one sees the $\alpha\text{-Fe}$ transition, but no surge in M below 570 °C because of the metastability of Fe_{1-x}O . The slightly more rapid increase in M seen on cooling below 400 °C is probably due to initial Fe_{1-x}O decomposition. The metastability of Fe_{1-x}O provides another demonstration of the wide variety of magnetic phenomena.

Magnetocrystalline anisotropy and spin reorientation in $\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}$

T. Ito, H. Asano, H. Ido, and M. Yamada

Department of Applied Physics, Tohoku Gakuin University, Tagajo 985, Japan

Magnetic measurements at various temperatures have been performed for loose powder and field-oriented samples of $\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}$ with $x=0, 0.05$, and 0.1 . The temperature dependences of spontaneous magnetization in these compounds are determined. It is found that a spin reorientation occurs at around $T=162$ K for $\text{Gd}_{0.95}\text{Dy}_{0.05}\text{Co}_4\text{B}$ and at around 225 K for $\text{Gd}_{0.9}\text{Dy}_{0.1}\text{Co}_4\text{B}$. The temperature dependences of magnetic anisotropy constants, $K_1(\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B})$, of $\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}$ with $x=0$ and 0.1 are determined. The anomalous temperature dependence of K_1 (GdCo_4B) is well explained by taking account of the Gd sublattice magnetic anisotropy due to the dipole-dipole interaction and the Co sublattice magnetic anisotropy similar to that in YCo_4B . The temperature dependence of the Dy sublattice magnetic anisotropy constant, $K_1(\text{Dy})$, has also been determined by making use of $K_1(\text{GdCo}_4\text{B})$ and $K_1(\text{Gd}_{0.9}\text{Dy}_{0.1}\text{Co}_4\text{B})$. © 1996 American Institute of Physics. [S0021-8979(96)31708-1]

I. INTRODUCTION

RCo_4B ($\text{R}=\text{rare earth}$) compounds have a hexagonal CeCo_4B -type structure,¹ which is derived from the CaCu_5 -type structure by replacing the $2c$ -site Co atoms by B atoms. In our previous work, the substitution effect of Dy for the magnetic properties of GdCo_4B were observed to investigate the magnetic state of Dy in the CeCo_4B -type structure.^{2,3} In this work, to confirm the magnetocrystalline anisotropy of Gd and Co sublattices as well as the very strong anisotropy of the Dy sublattice in the CeCo_4B -type structure, the magnetic measurements on $\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}$ with $x=0, 0.05$, and 0.1 have been extended to the higher temperature region.

II. SPECIMENS AND CRYSTAL STRUCTURE

Ingots of $\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}$ were prepared by melting raw materials of 99.9% purity for Gd, Dy, and B, and 99.99% for Co in an arc furnace. The ingots were melted eight times to homogenize the composition, and then annealed at 800°C for three days. The crystal structure has been confirmed by x-ray diffraction to be of the CeCo_4B -type structure. Field-oriented samples were prepared by solidifying the mixture of epoxy resin and the powdered specimen ($<32\text{ }\mu\text{m}$) in the magnetic field of 20 kOe at room temperature.

III. EXPERIMENTAL RESULTS AND DISCUSSION

The magnetization curves at various temperatures between 80 and 521 K have been measured in magnetic fields up to 20 kOe for loose powder samples of $\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}$ with $x=0, 0.05$, and 0.1 . Spontaneous magnetizations have been estimated by extrapolating the high field linear part of the magnetization curves to $H=0$, and plotted against temperatures in Fig. 1. The detailed figures above 300 K are also shown separately in the inset. The Curie temperature (T_C) and compensation temperature (T_{comp}) shown in the inset seem to decrease toward the values of 428 and 352 K for DyCo_4B ,⁴ respectively. An anomalous decrease of magnetization of about $0.4\text{ }\mu_B/\text{f.u.}$ (formula unit) in the temperature

regions around 150 and 230 K for the data of $x=0.05$ and $x=0.1$, respectively, is caused by a spin reorientation which will be shown later.

Next, the magnetization curves of field-oriented samples $\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}$ with $x=0, 0.05$, and 0.1 have been measured at various temperatures between 80 and 300 K . Some examples for GdCo_4B and $\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}$ with $x=0.05$ and 0.1 are shown in Figs. 2 and 3, respectively. It is seen that GdCo_4B has an axial anisotropy at all temperatures below $T_C=503\text{ K}$, while the spin reorientation occurs at around 160 and 230 K for $x=0.05$ and $x=0.1$, respectively.

To estimate the magnetocrystalline anisotropy constant K_1 for GdCo_4B and $\text{Gd}_{0.9}\text{Dy}_{0.1}\text{Co}_4\text{B}$, the magnetization curves at various temperatures have been analyzed by the following method. The linear parts of the magnetization curves along with the hard axis in the decreasing field are shifted in parallel so as to go through the origin, and then an anisotropy field H_a is defined as a field at which the shifted straight line reaches the saturation magnetization (M_s). The anisotropy constant K_1 calculated by the equation $K_1=(1/2)M_sH_a$ is plotted against temperature in Fig. 4 for GdCo_4B and in Fig. 5 for $\text{Gd}_{0.9}\text{Dy}_{0.1}\text{Co}_4\text{B}$, respectively. The anomalous temperature dependence of K_1 for GdCo_4B is ex-

FIG. 1. Spontaneous magnetization vs temperature for $\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}$ with $x=0, 0.05$, and 0.1 . Inset: detailed figures near the Curie and compensation temperatures (see the text).

FIG. 2. Some examples for magnetization curves of the field-oriented sample of GdCo_4B .

plained by the superposition of the anisotropies of the Gd and Co sublattices. The Gd-sublattice anisotropy of GdCo_4B was calculated by taking account of the Gd-Gd and Gd-Co dipole interactions within a sphere of radius of 1000 Å around the Gd atom in the crystal, and is shown by the dashed line in Fig. 4. By subtracting this Gd-sublattice anisotropy from the experimental data, we can obtain, as shown by the dotted chain line in Fig. 4, the anisotropy constant $K_1(\text{Co})$ for the Co sublattice in GdCo_4B . It is found that $K_1(\text{Co})$ changes its sign at $T/T_C=0.2$, which is a little lower than $T/T_C=0.4$ for YCo_4B ⁵ which is also shown by the double dotted chain line in Fig. 4.

The anisotropy constant of $\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}$ is approximately expressed by

$$K_1(\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}) = (1-x)K_1(\text{GdCo}_4\text{B}) + xK_1(\text{DyCo}_4\text{B}). \quad (1)$$

Since the left-hand side and the first term on the right-hand side have been obtained as shown in Figs. 5 and 4,

FIG. 4. Temperature dependence of the magnetocrystalline anisotropy constant K_1 for GdCo_4B . The dashed, dotted chain, and double dotted chain lines represent the magnetic anisotropy constant $K_1(\text{Gd})$ of the Gd sublattice due to the dipole-dipole interaction, $K_1(\text{Co})$ of the Co sublattice in GdCo_4B , and $K_1(\text{YCo}_4\text{B})$ of YCo_4B (Ref. 5), respectively (see the text).

FIG. 5. Temperature dependences of the magnetocrystalline anisotropy constants $K_1(\text{Gd}_{0.9}\text{Dy}_{0.1}\text{Co}_4\text{B})$ and $K_1(\text{Dy})$ per Dy atom. In $K_1(\text{Dy})$, \times are the values obtained from the magnetization curves for the field-oriented $\text{Gd}_{0.9}\text{Dy}_{0.1}\text{Co}_4\text{B}$ in Fig. 3, \bullet is determined from the spin reorientation temperatures of $\text{Gd}_{0.95}\text{Dy}_{0.05}\text{Co}_4\text{B}$ and $\text{Gd}_{0.9}\text{Dy}_{0.1}\text{Co}_4\text{B}$, and \circ is determined from the magnetization curve at $T=5$ K in our previous paper (Ref. 2) (see the text).

FIG. 3. Some examples for magnetization curves of field-oriented samples of $\text{Gd}_{0.95}\text{Dy}_{0.05}\text{Co}_4\text{B}$ and $\text{Gd}_{0.9}\text{Dy}_{0.1}\text{Co}_4\text{B}$.

FIG. 6. Temperature dependence of magnetization at $H=1$ kOe for $\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}$ with $x=0.05$ (\bullet) and $x=0.1$ (\circ). The temperature regions between the two arrows mean the tilted state regions. T_{SR} represents the spin reorientation temperature defined by the center of the tilted temperature region (see the text).

respectively, $K_1(\text{DyCo}_4\text{B})$ can be estimated by Eq. (1). By subtracting $K_1(\text{YCo}_4\text{B})$ ⁵ from $K_1(\text{DyCo}_4\text{B})$, we can obtain the temperature dependences for $K_1(\text{Dy})$ per Dy atom as shown in Fig. 5. By analyzing the magnetization curve at $T=5$ K in our previous data,² we have obtained the value indicated by the open circle (○) in Fig. 5. This value roughly agrees with the value of -21.8×10^{-15} ergs/Dy for $K_1(\text{Dy})$ of $\text{Gd}_{0.95}\text{Dy}_{0.05}\text{Co}_4\text{B}$ estimated in our previous work.³ Since the absolute value of $K_1(\text{Dy})$ in the low temperature region has a very large anisotropy energy compared with $K_1(\text{Gd})$ and $K_1(\text{Co})$ in GdCo_4B , it is found that only a small substitution of Dy changes the axial anisotropy of GdCo_4B to the planar one.

To investigate the spin reorientation in $\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}$ with $x=0.05$ and 0.1 , temperature dependences of magnetization at $H=1$ kOe have been observed as shown in Fig. 6. From this figure, $\text{Gd}_{1-x}\text{Dy}_x\text{Co}_4\text{B}$ with $x=0.05$ and 0.1 has a

tilted state between the temperatures indicated in Fig. 6. They have axial and planar anisotropies in the higher and the lower temperature regions, respectively. Defining the spin reorientation temperature T_{SR} by the center of the tilted temperature region, we get $T_{\text{SR}}=162$ and 225 K for $x=0.05$ and 0.1 , respectively. At T_{SR} , the left-hand side of Eq. (1) must be zero, so $K_1(\text{Dy})$ can be determined by making use of $K_1(\text{GdCo}_4\text{B})$ in Fig. 4. The values determined by this method are shown by the filled circles (●) in Fig. 5.

Dependence of energy dissipation on annealing temperature of melt-spun NdFeB permanent magnet materials

Z. Gao, D. C. Jiles, D. J. Branagan, and R. W. McCallum
Ames Laboratory, Ames, Iowa 50011

A model of magnetic hysteresis which was developed originally for soft magnetic materials has been applied to melt-spun ribbons of Nd₂Fe₁₄B-based material. The crucial ideas in the model description of hysteresis center on a dissipation of energy due to hysteresis which is proportional to the change in magnetization. The Nd₂Fe₁₄B material was melt-spun amorphous and then annealed for a period of 24 h at temperatures ranging from 700 to 950 °C. This resulted in different grain sizes, depending on annealing temperature. Consequently the hysteresis curves represent the properties of the material as a function of both annealing temperature and grain size. It was found that the magnetic properties varied systematically with annealing temperature, and hence grain size, as would be expected. When modeling the magnetic properties it was found that the model parameters also varied systematically, in particular, the energy dissipation parameter k was to a first approximation a simple linear function of the annealing temperature and decreased with increasing annealing temperature as a result of grain growth. Therefore, this study revealed a basic relationship between materials processing conditions, microstructure, model parameters, and magnetic properties. © 1996 American Institute of Physics. [S0021-8979(96)31808-8]

I. INTRODUCTION

Permanent magnet materials based on Nd₂Fe₁₄B, have been the focus of attention of the hard magnet community for the last ten years. A wide range of materials properties has been reported,¹⁻⁴ but the overriding property of these materials has been their high maximum energy product, which can exceed 50 MG Oe (~400 kJ/m³). The latest results reported indicate a maximum energy product of 54 MG Oe (430 kJ/m³).⁵

While much work has been devoted to the processing and production of these alloys with even greater energy products, remanences, and coercivities, little attention has been paid to the description of these properties in terms of a physical model. Nevertheless, this is important because a model can provide a direct link between microstructure and magnetic properties. In this paper we focus on the application of a model, which was developed originally for soft magnetic materials, in which the crucial idea in the description of hysteresis centers on a dissipation of energy due to hysteresis which is proportional to the change in magnetization. This idea, which was originally developed through a consideration of domain wall displacement, leads to a pair of differential equations for hysteresis which are valid for a wider range of behavior provided that the energy dissipation is proportional to the change in energy.

The hysteresis equations for the model under consideration here have been described in detail elsewhere.⁶ They are given here for completeness. The hysteresis-free curve, or anhysteretic curve, is described by

$$M_{an}(H) = M_s \left[\coth \left(\frac{H + \alpha M}{a} \right) - \left(\frac{a}{H + \alpha M} \right) \right],$$

where M_s is saturation magnetization, α is the internal coupling of the domain magnetizations, and $a = k_B T / \mu_0 \langle m \rangle$, where k_B is the Boltzmann constant, T is the temperature, μ_0

is the permeability of free space, $\langle m \rangle$ is the mean effective domain size, M_{an} is the anhysteretic magnetization, and H is the magnetic field.

The hysteresis curve is given by

$$\frac{dM(H)}{dH} = \frac{M_{an}(H) - M_{irr}(H)}{k\delta - \alpha[M_{an}(H) - M_{irr}(H)]} + c \left(\frac{dM_{an}(H)}{dH} - \frac{M_{an}(H) - M_{irr}(H)}{k\delta - \alpha[M_{an}(H) - M_{irr}(H)]} \right).$$

These equations can then be solved to give the hysteresis curves of the material. Here k is the energy loss per unit change in magnetization and c , which gives a measure of the amount of the reversible domain wall motion, can be related directly to the domain wall surface energy.

It should be noted that the anhysteretic curve used in the model calculation here is for isotropic materials. Therefore the model cannot be expected to exactly fit the part of the experimental curve where the change of magnetization is due to the reversible rotation of the magnetic moments with respect to the randomly oriented crystallographic easy axis.

II. EXPERIMENT

Amorphous Nd₂Fe₁₄B was prepared by melt spinning with a wheel speed of 45 m/s. The resulting samples were annealed at temperatures ranging from 750 to 950 °C for a period of 24 h. The hysteresis data were taken using a Quantum Design dc SQUID. In order to make the measurements, about 40 ribbons were laid parallel in two layers on double-sided adhesive tape. Then the tape was wrapped onto a quartz rod. To minimize demagnetizing effects, the long axis of the ribbons was situated parallel to the applied magnetic field. No corrections due to demagnetization effects were made.

FIG. 1. Measured and modeled hysteresis curves for specimen 1. The measured data are the circles, the model calculation is the curve.

III. RESULTS

The hysteresis curves for seven specimens of NdFeB were measured and representative samples of these measurements are shown in Figs. 1–3. The magnetic properties changed progressively from one specimen to the next as the annealing temperature increased from 700 to 950 °C. For example, the coercivity in the specimen annealed at 700 °C was 487 kA/m while in the specimen annealed at 950 °C it was found to be 97 kA/m. In addition the differential permeability was greater at all points on the hysteresis loop in the materials annealed to higher temperatures, and there was a general decrease in remanence as the annealing temperature increased. A summary of the measured magnetic properties is given in Table I.

The grain sizes in specimens 2 and 7 were measured. These were 20–156 nm (with a mean of 75 nm) in specimen 2; and 154–740 nm (with a mean of 361 nm) in specimen 7.

IV. MODELING OF MAGNETIC PROPERTIES

The magnetic properties were used to determine the hysteresis model parameters. The values of the model parameters are shown in Table II for each of the materials investigated. From this it is clear that there was a progressive

FIG. 2. Measured and modeled hysteresis curves for specimen 3. The measured data are the circles, the model calculation is the curve.

FIG. 3. Measured and modeled hysteresis curves for specimen 6. The measured data are the circles, the model calculation is the curve.

change in the hysteresis parameters such as k , the energy dissipation, and a , the effective domain density, as the annealing temperature was changed.

A comparison of the measured and modeled hysteresis curves is shown in Figs. 1–3. In the region near the coercive field, the model fits the data reasonably well. The model cannot, however, be expected to fit the part of the experimental curve where the change of magnetization is due to the reversible rotation of the magnetic moments with respect to the randomly oriented crystallographic easy axis, and in fact there are systematic differences between the measured and modeled curves in this region. If the anhysteretic curve of Eq. (1) is replaced by the minimum energy curves calculated by the Stoner–Wohlfarth model,⁷ it would appear that the theory will fit the data rather well. Nevertheless, the present modeled values of magnetization are within 10% of the measured values along most of the curve, with some deviations of up to 20% in limited regions close to the knee of the demagnetization curve.

The variation of the energy dissipation parameter with annealing temperature is shown in Fig. 4. To a first approximation this appears to be linear with the relationship

$$k = k_0 - k_1 T_{\text{ann}},$$

where $k_0 = 2 \times 10^6 \text{ A m}^{-1}$, and $k_1 = 2 \times 10^3 \text{ A m}^{-1} \text{ C}^{-1}$.

V. CONCLUSIONS

The effects of different annealing temperatures on the magnetic properties of melt-spun NdFeB permanent magnet material have been studied. The measured hysteresis curves of these specimens have been used to calculate the model parameters for an established hysteresis model developed

originally for soft magnetic materials. A comparison has been made between the measured and modeled hysteresis curves, showing good agreement, although indicating that the model could be made more appropriate for these materials by the introduction of anisotropy. It was found that the model energy dissipation parameter, k , which represents the rate of energy loss per unit change in magnetization, decreased linearly with annealing temperature.

Department of Applied Science, Brookhaven National Laboratory, Upton, New York 11973

F. Pourarian

Carnegie Mellon Research Institute, Carnegie Mellon University, Pittsburgh, Pennsylvania 15230-2950

Quantitative evidence of a ferromagnetic Fe-rich minor phase present in both melt-quenched/die-upset and sintered magnets based on the $\text{Nd}_2\text{Fe}_{14}\text{B}$ composition is presented. Full hysteresis loops were obtained at elevated temperatures ($650 \text{ K} \leq T \leq 800 \text{ K}$) and were subsequently decomposed to obtain the saturation magnetization M_s of the minor phase as well as the paramagnetic slope of the 2-14-1 major phase as a function of temperature. Assuming a composition of pure iron, the calculated volume % of the impurity phase in the die-upset magnets is consistent with that obtained from previous observations of the widths and geometry of the intergranular phase found in the same magnets. The magnetization of the ferromagnetic impurity phase in the melt-quenched magnets decreases more rapidly than that of pure iron; extrapolation indicates a Curie temperature in the range $925 \text{ K} < T < 975 \text{ K}$. The paramagnetic susceptibility of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ main phases exhibits Curie-Weiss behavior with the same paramagnetic Curie temperature for both sintered and die-upset samples. The Curie constants differ, however, probably due to the different degrees of crystallographic alignment. © 1996 American Institute of Physics. [S0021-8979(96)42108-9]

INTRODUCTION

The identification of dominant reversal mechanisms of magnets based on the $\text{Nd}_2\text{Fe}_{14}\text{B}$ composition is important to both the fundamental understanding of the physics governing their magnetic behavior as well as to the engineering of increasingly economical and effective magnets for the world market. It is generally agreed upon in the literature that 2-14-1-based magnets made by the sintering process achieve their coercivity by the nucleation of reversed domains.^{1,2} In contrast, the limiting mechanism which controls magnetic reversal in the $\text{RE}_2\text{Fe}_{14}\text{B}$ die-upset magnets produced by melt-quenching methods remains an unsettled question in the literature.³ In particular, the role that intergranular interactions, both magnetostatic and exchange, play in aiding or hindering magnetic reversal is attracting attention in both the theoretical^{4,5} and the experimental^{6,7} arenas. Characteristics such as relative grain orientation, size, and what consequences the existence and nature of intergranular phases have upon the global reversal mechanism is presently being questioned.

While it is a known fact that bcc iron does occur in sintered magnets,⁸ recent work has demonstrated the existence of a previously unknown iron-rich grain-boundary phase in melt-quenched, thermomechanically processed magnets fabricated by General Motors Research and Development (R&D) Center. This iron-rich grain-boundary phase

was identified and characterized by two independent transmission electron microscopy (TEM) methods: high-resolution analytical electron microscopy, using a nominal 5 Å probe⁷ and low-angle dark-field imaging based on inner-potential differences at the grain boundaries.⁹ Characterization of the hysteretic properties of the same die-upset samples at elevated temperatures has yielded data that suggests nucleation-controlled magnetization,⁷ as well as the presence of an unknown ferromagnetic phase.¹⁰ In this paper we present further characterization of the unknown ferromagnetic phase in a selection of compositionally related magnets produced by both melt-quenched and sintering methods.

EXPERIMENTAL METHODS

Hysteresis loops of 2-14-1-based magnets fabricated by both melt-quenching and sintering methods were measured with SQUID magnetometry at temperatures in the range $650 \text{ K} \leq T \leq 800 \text{ K}$. The bulk compositions, processing conditions and the dimensions of the magnets studied are given in Table I. Die-upset, melt-quenched magnets made by standard hot deformation processing methods¹¹ were obtained from General Motors R&D Center. Sintered magnets were fabricated by vacuum-sintering at 1080°C for 1 h and then post-sintered for 4 h at temperatures ranging from 600°C to 950°C . Magnetic measurements were made on samples ma-

TABLE I. Description of samples.

Processing	Name	Bulk composition	Dimensions
Die-upset (MQ-3)	DU1418	$\text{Nd}_{13.75}\text{Fe}_{80.25}\text{B}_6$	1.423 mm×1.217 mm×1.933 mm

FIG. 1. Measured hysteresis loop of sample DU1929 measured $T=800$ K, decomposed into the paramagnetic contribution from the 2-14-1 phase and the ferromagnetic contribution from the additional Fe-rich phase.

chined down to the appropriate dimensions to fit inside quartz capillary tubes that were evacuated to a base pressure of 5.6×10^{-5} Torr and sealed with Zr turnings to avoid oxidation during measurement. Prior to each hysteresis loop measurement the magnets were brought to temperature and then saturated in an applied field of $+5.5$ T.

The resultant hysteresis loops were corrected for demagnetization using a method previously described,⁷ and the magnetic signals from the 2-14-1 matrix phase and the unknown phase were separated as follows: The hysteresis loop is the superposition of the main-phase paramagnetic signal and the unknown phase ferromagnetic signal.¹² At relatively large fields ($H_{\text{int}} > 1000$ G) the signal consists almost entirely of the paramagnetic contribution, displaced from the origin by an amount equal to the saturation magnetization of the unknown phase. Thus a linear fit to the high-field portion of the total signal yields both the paramagnetic slope and the saturation magnetization of the ferromagnetic phase. The paramagnetic contribution is then subtracted from the total signal to yield the ferromagnetic signal. Figure 1 shows a corrected hysteresis loop measured at 800 K for the Pr-based die-upset sample DU1929 that has been decomposed into the 2-14-1 paramagnetic contribution and the additional phase ferromagnetic contribution. During the course of this work it was found that the M_s (y -intercept) determination was very sensitive to the points selected for the linear fit, so care was taken to only involve those measurements of the loop for $H_{\text{int}} \geq 1500$ G. In contrast, the determination of the paramagnetic slope of the 2-14-1 main phase was found to be quite insensitive to the choice of points to fit. From multiple measurements performed on the same sample the error in M_s is estimated to be on the order of 3%.

In order to obtain a quantitative estimation of the amount of ferromagnetic phase present within the volume of the samples at $T > T_c(2-14-1)$, it was necessary to assume that the phase consisted of pure iron, with a saturation magnetization of approximately 1370 emu/cc at 800 K. It is also important to consider the contribution to the total magnetic signal due to the probable surface disproportionation and the limited oxidation of the 2-14-1 main phase into such possible products as α -Fe, Nd_2O_3 , Fe_2O_3 , and BO_x . Using results of the depth of the disproportion layer obtained on similar

FIG. 2. Saturation magnetizations as a function of temperature for the unknown ferromagnetic phases. The magnetization curve of pure iron, dashed line, is included for reference.

samples subjected to similar atmospheric and temperature conditions by Hirosawa *et al.*,¹³ an upper-bound estimate of the contribution from the corroded surface to the total signal was computed and subtracted from the unknown $M_s(T)$ signal. By assuming the existence of layer of α -Fe that covers the entire surface of each sample and possess a thickness of 100 nm (the upper limit to the thickness as reported by Hirosawa), 7–8 G, depending upon the temperature, was subtracted from the measured saturation magnetization M_s of each sample.

RESULTS AND DISCUSSION

The saturation magnetization of the unknown ferromagnetic phase and the paramagnetic slopes of the 2-14-1 matrix phase that result from the decomposition of the hysteresis loops are shown in Figs. 2 and 3 and in Table II. For reference, the reduced magnetization curve as a function of temperature for pure iron is included in Fig. 2.¹⁴ The M_s vs temperature trend of the die-upset FeNdB resembles that for pure iron but falls faster, implying that the unknown ferromagnetic phase has lower Curie temperature than iron. Extrapolation of the magnetization curve of DU1418 yields a

FIG. 3. Reciprocal paramagnetic susceptibilities of the 2-14-1 matrix phases as functions of temperature.

TABLE II. Comparison of volume percentages of grain boundary phase and unknown phase.

Sample	Bulk composition	Vol % of grain boundary phase calculated from microstructural characterization	Vol % of unknown phase calculated from magnetic measurements $T=800$ K
DU1418	Nd _{13.75} Fe _{80.25} B ₆	0.33	0.095
DU1929	Pr _{13.75} Fe _{80.25} B ₆	0.58	0.109

Curie temperature in the range $925\text{ K} < T < 975\text{ K}$ for the unknown ferromagnetic phase. This result underscores the expectation that the grain boundary phase does not consist of pure iron. The magnetization trend for the unknown ferromagnetic phase present in the sintered FeNdB does not look at all like that for pure iron, though other researchers have verified the presence of α -Fe in sintered magnets.

Earlier detailed studies on the microstructures of DU1418 and DU1929 (Refs. 7 and 9) have indicated the presence of an Fe-rich intergranular phase. This phase was found to be amorphous, and its presence is dependent upon the nature of the grain boundary in question; for example, there appears to be no intergranular phase in (001) twist boundaries parallel to the tetragonal basal plane. The average width of the intergranular phase was found to be $8\text{--}12\text{ \AA}$ in the Nd-based magnet and $15\text{--}20\text{ \AA}$ in the Pr-based magnet. The average dimensions of the deformed grains are $600\text{ nm} \pm 150\text{ nm}$ in length by $150\text{ nm} \pm 75\text{ nm}$ in width. Using these characterizations, and making the assumption that the microstructure of the melt-quenched samples is completely comprised of uniformly deformed square platelets, Table II gives the results for the expected vol % of Fe-rich grain-boundary phase. Quantitative determinations of the vol % of grain-boundary phase calculated from magnetic measurements made on the other samples whose microstructures have not been carefully examined with HRTEM methods are included in Table III. Previous determinations indicate that the vol % of pure iron in sintered magnets is on the order of $2\text{--}10\text{ vol \%}$,¹² the results presented in Table III for the sintered magnets show significantly less excess iron.

The determination of the vol % of grain boundary phase of the die-upset magnets calculated from the microstructural

characterizations exceeds that calculated from the magnetic measurements by a factor of roughly 3.5 for the Nd-based sample and 5 for the Pr-based sample. However, this is actually an encouraging agreement when one considers the extreme inhomogeneity in both composition and structure of the melt-quenched and die-upset samples.¹⁵ Additionally, previous determinations of the composition of the grain boundary phase⁷ confirm that it does not consist of pure iron, and thus the vol % determined from microstructural considerations is inherently overestimated. It is thus very likely that the source of the ferromagnetic signal at elevated temperatures is, at least in part, due to the Fe-rich intergranular phase.

The reciprocal paramagnetic susceptibilities of the 2-14-1 matrices of both types of magnets as a function of temperature are presented graphically in Fig. 3. In both cases a Curie-Weiss dependence is observed, extrapolating to the same value, approximately 600 K, of the paramagnetic Curie temperature. This temperature is slightly higher than the actual Curie temperature of 585 K,¹⁶ as is generally observed to be the case for ferromagnets.¹⁷ The differences between the Curie constants (slopes) of the two materials may reflect intrinsic differences between the 2-14-1 matrices found in the die-upset magnet versus the sintered magnet, such as compositional or crystallinity differences. However, since the paramagnetic Curie temperatures are the same, this behavior probably reflects a difference in the bulk texture of the two types of magnets.

NdFe_{10.7}TiM_{0.3}(M=B, Ti) has been studied with x-ray diffraction, Mössbauer spectroscopy, and a vibrating sample magnetometer. The alloys were prepared by arc-melting under an argon atmosphere. The NdFe_{10.7}TiB_{0.3} exhibits a pure single phase, whereas the NdFe_{10.7}Ti_{1.3} contains some α -Fe, from x-ray and Mössbauer measurements. The NdFe_{10.7}TiB_{0.3} has the ThMn₁₂-type tetragonal structure with $a_0=8.587$ Å and $c_0=4.788$ Å. The Curie temperature (T_C) is 570 K from Mössbauer spectroscopy performed at various temperatures ranging from 13 to 770 K. Each spectrum below T_C was fitted with five subspectra of Fe sites in the structure ($8i_1$, $8i_2$, $8j_1$, $8j_2$, and $8f$). The area fraction of the subspectra at room temperature are 16.4%, 8.2%, 14.8%, 21.3%, and 39.3%, respectively. Magnetic hyperfine fields for the Fe sites decrease on the order of $H_{\text{hf}}(8i) > H_{\text{hf}}(8j) > H_{\text{hf}}(8f)$. The average hyperfine field $H_{\text{hf}}(T)$ of the NdFe_{10.7}TiB_{0.3} shows a temperature dependence of $[H_{\text{hf}}(T) - H_{\text{hf}}(0)]/H_{\text{hf}}(0) = -0.39(T/T_C)^{3/2} - 0.17(T/T_C)^{5/2}$ for $T/T_C < 0.7$, indicative of spin-wave excitation. Annealing the alloy at around T_C for 60 min resulted in a two phase microstructure consisting of a ThMn₁₂-type structure and α -Fe. © 1996 American Institute of Physics. [S0021-8979(96)31908-4]

I. INTRODUCTION

The Nd₂Fe₁₄B and related Fe-rich Fe-R-B permanent magnets have large coercivities and high energy products $(BH)_{\text{max}}$ in excess of 45 MG Oe.^{1,2} The shortcomings of the Fe-R-B magnets and their derivatives have led to the search for novel Fe-rich compounds that might serve as alternatives for starting materials in permanent magnets. The R(Fe, M)₁₂ (R=Sm, Nd, Pr, Gd; M=Ti, V, Mo, Cr) compounds with the tetragonal ThMn₁₂-type structure have been reported for the potential candidates for permanent magnet development. We concentrate on the Nd(Fe, M)₁₂ compounds, where the cost of Nd is much lower than that of Sm. The substitution effects of Ti for Fe in Nd(Fe, Ti)₁₂ have been investigated by several researchers,^{3,4} and the Curie temperature, anisotropy field, and the saturation magnetization were found to increase with Ti substitution. Neutron diffraction experiments⁵ for a ThMn₁₂-type R(Fe, M)₁₂ structure have shown that the iron atoms occupy the $8j$ and $8f$ sites preferentially, and the M atoms occupy $8f$ sites with the rest on $8i$ sites.

In this study, we have to tried to prepare NdFe_{10.7}TiM_{0.3}(M=B, Ti) compounds by substituting B for Ti in order to enhance the intrinsic magnetic properties of the NdFe₁₁Ti-type compound. The magnetic and crystallographic properties are studied using Mössbauer spectroscopy, a vibrating sample magnetometer (VSM), and x-ray diffraction techniques.

II. EXPERIMENTAL TECHNIQUE

Alloys of NdFe_{10.7}TiM_{0.3}(M=B, Ti) were prepared by arc-melting under an argon gas atmosphere. The buttons of NdFe_{10.7}TiM_{0.3}(M=B, Ti) alloys were ground into powders under 45 μm in size for Mössbauer measurements. A Mössbauer spectrometer of the electromechanical type⁶ was used in the constant-acceleration mode. A ⁵⁷Co single-line source in a rhodium matrix was used at room temperature. To pro-

duce a uniform thickness over the area of the Mössbauer absorber, each sample was mixed with boron nitride powder and clamped between two beryllium disks 0.005 in. thick and 1 in. diam. The low temperature data were obtained using an APD CS-202 displax closed-cycle refrigeration system with a DMX-20 Mössbauer vacuum shroud interface.

X-ray-diffraction patterns of the samples were obtained with Cu K_α radiation. A slow scanning speed of 0.25° advance in 2 θ /min was used in order to optimize resolution of the closely spaced reflections.

III. RESULTS AND DISCUSSION

X-ray diffraction patterns for NdFe_{10.7}Ti_{1.3} and NdFe_{10.7}TiB_{0.3} obtained at room temperature. Every peak in the patterns for NdFe_{10.7}TiM_{0.3}(M=B, Ti) can be indexed on the basis of the tetragonal ThMn₁₂-type unit cell. The lattice constants and Curie temperatures of NdFe_{10.7}TiM_{0.3}(M=B, Ti) are listed in Table I. The NdFe_{10.7}TiB_{0.3} alloy, by substituting B for Ti, exhibits a pure single phase of ThMn₁₂-type structure with the following unit cell constants: $a_0=8.587$ Å and $c_0=4.788$ Å. However, NdFe_{10.7}Ti_{1.3} has a nearly single ThMn₁₂-type phase except for a small amount of the α -Fe phase.

Figures 1 and 2 show some of the Mössbauer spectra of NdFe_{10.7}TiB_{0.3} measured at various absorber temperatures from 13 to 770 K. Using a least-squares computer program, five sets of six Lorentzian lines corresponding to the $8i_1$, $8i_2$, $8j_1$, $8j_2$, and $8f$ sites were fitted to the Mössbauer spectra below Curie temperature, T_C under the well-known restraints,⁷ which are valid when the quadrupole interaction is much weaker than the magnetic hyperfine interaction.

In Nd(Fe, M)₁₂ structure, the distribution of M atoms may cause a distribution of Fe nearest neighbors in each Fe site, which results in quite broad outer lines in the Mössbauer spectra due to a distribution of hyperfine fields. By the neutron diffraction studies, an acceptable fit of the Mössbauer

FIG. 1. Mössbauer spectra of NdFe_{10.7}TiB_{0.3} at low temperature.

FIG. 2. Mössbauer spectra of NdFe_{10.7}TiB_{0.3} near the Curie temperature.

spectra of the NdFe_{10.7}TiB_{0.3} was performed using five sites ($8i_1$, $8i_2$, $8j_1$, $8j_2$, and $8f$).⁸ The resulting area of the sub-spectra $8i_1$, $8i_2$, $8j_1$, $8j_2$, and $8f$ at room temperature are 16.4%, 8.2%, 14.8%, 21.3%, and 39.3%, respectively.

The temperature dependence of the isomer shifts, relative to α -Fe at room temperature, is shown in Fig. 3. The shifts for each site increase with decreasing temperature, consistent with the second-order Doppler shift.⁹

Figure 4 shows the temperature dependence of magnetic hyperfine field for NdFe_{10.7}TiB_{0.3}. The magnetic hyperfine fields for the Fe sites then decrease in the order, $H_{hf}(8i) > H_{hf}(8j) > H_{hf}(8f)$.

Figure 5 shows the fractional change of the average magnetic hyperfine field, $[H_{hf}(T) - H_{hf}(0)]/H_{hf}(0)$, as a function of T . The magnetic hyperfine field decrease with increasing temperature according to¹⁰

$$\frac{H_{hf}(T) - H_{hf}(0)}{H_{hf}(0)} = -B_{3/2} \left(\frac{T}{T_C} \right)^{3/2} - C_{5/2} \left(\frac{T}{T_C} \right)^{5/2}. \quad (1)$$

A least-squares fit of Eq. (1) to the magnetic hyperfine field data gave $B_{3/2} = 0.39 \pm 0.05$ and $C_{5/2} = 0.17 \pm 0.05$. This value of $B_{3/2}$ for NdFe_{10.7}TiB_{0.3} is much larger than those of α -Fe

and Ni: $B_{3/2} = 0.12$ for Ni and $B_{3/2} = 0.11$ for α -Fe.¹¹ So, spin waves having long wavelengths are excited in the alloys rather than in α -Fe and Ni.

Annealing the NdFe_{10.7}TiB_{0.3} alloys at around Curie temperature, $T_C = 570$ K,¹² for 60 min resulted in a two phase microstructure consisting of ThMn₁₂ and α -Fe and according to the percentage of ThMn₁₂ and α -Fe phases present: 93 wt % ThMn₁₂/7 wt % α -Fe. When the alloys are annealed above the Curie temperature the α -Fe phases increased linearly as a function of the temperatures. Mössbauer results on the alloy showed 20 wt % ThMn₁₂ and 80 wt % α -Fe at

FIG. 3. Dependence of isomer shifts, δ , on the temperature in NdFe_{10.7}TiB_{0.3}.

TABLE I. Lattice constants, a_0 and c_0 , and the Curie temperature, T_C for NdFe_{10.7}TiM_{0.3} (M=B, Ti).

Sample	a_0 (Å)	c_0 (Å)	T_C (K)
NdFe _{10.7} Ti _{1.3}	8.607	4.790	553
NdFe _{10.7} TiB _{0.3}	8.587	4.788	570

FIG. 4. Dependence of magnetic hyperfine fields, H_{hf} , on the temperature in $\text{NdFe}_{10.7}\text{TiB}_{0.3}$.

around 770 K for 60 min. Since the $\text{NdFe}_{10.7}\text{TiB}_{0.3}$ alloy above the Curie temperature contains the α -Fe phase, the remanent magnetization changed to a low but nonzero value.

The temperature dependence of the magnetic moment of $\text{NdFe}_{10.7}\text{TiB}_{0.3}$ under an applied field $H=10$ kG is shown in Fig. 6. The solid circle indicates the normalized magnetic hyperfine field taken from the Mössbauer spectra. The magnetic moment measured as a function of temperatures with a VSM are marked with a solid line. These data show the magnetic moments measured with Mössbauer spectroscopy

FIG. 5. Fractional change of the average magnetic hyperfine field; H_{hf} , as a function of $(T/T_c)^{3/2}$.

FIG. 6. Temperature dependence of the magnetic moment under an applied field of 10 kG for $\text{NdFe}_{10.7}\text{TiB}_{0.3}$. The solid circles are average normalized magnetic hyperfine fields taken from Mössbauer spectra.

and VSM agree with each other very well below the Curie temperature (570 K). Above the Curie temperature, VSM data show that the magnetic moments increase again. The formation of α -iron is the main reason for the increasing moment that is conformed with the Mössbauer experiment as shown in Fig. 2. By substituting Ti by B, it is concluded that B strongly affects the increase of both the Curie temperature and the magnetization.

Structure and magnetic properties of mechanically alloyed Nd(Fe,V)₁₂N_x compounds

Jun Yang, Ou Mao, and Z. Altounian

Center for the Physics of Materials, Department of Physics, McGill University, 3600 University Street, Montréal, Québec H3A 2T8, Canada

The structure and magnetic properties of Nd(Fe,M)₁₂N_x (M=Ti,Mo,V) compounds prepared by mechanical alloying (MA) have been studied using x-ray diffraction and magnetic measurements. It is found that after annealing, single-phase Nd(Fe,V)₁₂ compounds can be obtained over a large composition range, but can only be obtained in Nd(Fe,V)₁₁ after MA. The crystallization of stoichiometric compounds at 750–950 °C always produces a small amount of α -Fe(V) in addition to the 1:12 phase. Below 750 °C, the crystallization is not complete and large amounts of α -Fe(V) are present. When nitriding at 450 °C, the α -Fe(V) phase disappears accompanied by the formation of an amorphous phase and a 1:7 nitride phase. The crystallized phase retains the 1:12 structure when nitriding at 480 °C. The highest coercivity of 8.8 kOe has been obtained for the NdFe_{10.5}V_{1.5}N_x compound. The difference between the coercivities of MA Nd(Fe,V)₁₂N_x, Nd(Fe,Mo)₁₂N_x, NdFe₁₁TiN_x, and Sm₂Fe₁₇N_x compounds is attributed to their different crystallization behavior and phase stability during nitrogenation. © 1996 American Institute of Physics. [S0021-8979(96)32008-9]

I. INTRODUCTION

Nd(Fe,M)₁₂N_x compounds (M=Ti,Mo,V), which have high Curie temperature, high saturation magnetization, and large (easy *c*-axis) anisotropy field, are promising candidates for permanent magnet applications.^{1–4} Nd(Fe,V)₁₂N_x compounds show better intrinsic magnetic properties than Nd(Fe,Mo)₁₂N_x compounds with similar coercivities. They also have much higher coercivities compared to NdFe₁₁TiN_x compounds. This indicates that Nd(Fe,V)₁₂N_x compounds are more attractive as permanent magnets. As mechanical alloying (MA) can produce high coercivity in permanent magnets due to the nanometer sized grains, we have investigated the structural and magnetic properties of Nd(Fe,M)₁₂N_x compounds prepared by mechanical alloying.

II. EXPERIMENTAL METHODS

Alloys of Nd(Fe,M)₁₂ compounds with M=Ti,V,Mo were prepared by induction melting of 99.9 wt % pure materials in a purified argon atmosphere in a cold crucible. An additional amount of Nd (3 wt %) was added to compensate for its loss in the preparation process. The ingots were wrapped in a tantalum foil and sealed into a vacuum silica tube, then annealed at 900–1100 °C for 1 week. For MA, the annealed compounds were crushed into particles of diameter less than 10 μ m and sealed into a steel vial with two stainless steel balls in the ratio of powder to ball of 1 to 10 in an argon atmosphere. MA was done in a high energy Spex 8000 mixer/mill for 10–20 h. Crystallization was carried out in the temperature range from 600 to 950 °C for 0.5–3 h in an argon atmosphere. The recrystallized compounds were nitrided at 400–600 °C for 3 h in a thermopiezic analyzer (TPA). Structural and phase analysis studies were done with an automatic Nicolet–Stöe powder diffractometer with Cu *K α* radiation and from thermomagnetic scans using a Perkin–Elmer thermogravimetric analyzer (TGA) in a small field gradient. Magnetic hysteresis loops were measured on a

vibrating sample magnetometer operating in a field of up to 1.5 T and in a pulsed field magnet in a field of up to 17 T at 300 K.

III. RESULTS AND DISCUSSION

A. Phase transformation during MA and crystallization

Single-phase Nd(Fe_{1–*x*}V_{*x*})₁₂ compounds can be obtained for *x*=0.125–0.17 and *y*=11–13 after annealing at 950 °C for 1 week. After MA, a mixture of α -Fe(V) and an amorphous phase is formed. The phase composition after crystallization depends on the composition of the compounds and annealing temperature. Crystallizing the stoichiometric or slightly Fe(V) rich compounds at 750–950 °C always produces a small amount of α -Fe(V) in addition to the 1:12 phase. Below 750 °C, the crystallization is not complete and large amounts of α -Fe(V) are present. Single phase 1:12 compounds can be obtained by crystallizing a MA Nd-rich Nd(Fe_{0.83}V_{0.17})₁₁ compound. As an example, Fig. 1 shows the x-ray diffraction patterns of a NdFe_{10.5}V_{1.5} compound after annealing (a), after MA (b), after crystallizing at 750 °C for 3 h (c), at 850 °C for 3 h (d), and a Nd(Fe_{0.83}V_{0.17})₁₁ compound after crystallizing at 850 °C for 3 h (e). Rare earth transition metal intermetallic compounds are brittle in nature because of the lack of slip systems available. This is a consequence of the large unit cell and noncubic symmetry of the structure. During the MA process, mechanical forces induce lattice distortions and defects thus increasing the free energy of the compounds. Eventually, the so-called mechanically driven disorder and phase transformation takes place. If the amount of one element is too large, it does not mix fully with other elements, and a homogeneous amorphous phase, similar to the melt-spun case, cannot be obtained. Instead, a mixture of an amorphous phase and a metal phase with small grains will be formed, which can be observed directly from the broadening of the α -Fe(V) peak in Fig. 1(b).

FIG. 1. X-ray diffraction patterns of $\text{NdFe}_{10.5}\text{V}_{1.5}$ in annealed state (a), MA state (b), after crystallizing at 750 °C for 3 h (c), after crystallizing at 850 °C for 3 h (d), and $\text{Nd}(\text{Fe}_{0.83}\text{V}_{0.17})_{11}$ after crystallizing at 850 °C for 3 h (e).

Upon annealing, the amorphous phase will either react directly with Fe(V) to form the ThMn_{12} structure or it will first crystallize into small grain-sized crystals followed by the reaction. Therefore, the crystallizing temperature and time will affect the phase composition and the final grain size of the product as shown in Figs. 1(c) and 1(d). In addition, as it is necessary to add a third element to stabilize the 1:12 phase, the recrystallized phases will also depend, for a given temperature, on the composition of alloying elements M. The composition and temperature range for the formation of $\text{NdFe}_{12-x}\text{M}_x$ are: (i) for Mo, x from 0.8 to 4.5 and below the melting point, (ii) for V, x from 1.2 to 2.5 and below 950 °C, and (iii) for Ti, x from 0.8 to 1.2 and above 1100 °C. This can explain why annealing MA $\text{Nd}(\text{Fe},\text{Mo})_{12}$ easily produces a single phase, but for $\text{Nd}(\text{Fe},\text{V})_{12}$, it is only achieved in the Nd- and V-rich $\text{Nd}(\text{Fe}_{0.83}\text{V}_{0.17})_{11}$ compound as shown in Fig. 1(e). On the other hand, the TbCu_7 -type phase and $\alpha\text{-Fe}(\text{Ti})$ are formed when crystallizing MA $\text{NdFe}_{11}\text{Ti}$. Certainly, the solid solubility of V, Ti, and Mo in Fe can also play a critical role as the solubility of V in Fe is much larger than those of Ti and Mo.

B. Phase transformation during nitrogenation

As mentioned above, for the compounds annealed below 750 °C, the crystallization is not complete and large amounts of $\alpha\text{-Fe}(\text{V})$ are present together with the 1:12 phase. Upon nitriding these compounds at 450 °C, the $\alpha\text{-Fe}(\text{V})$ phase disappears accompanied by the formation of an amorphous phase and a 1:7 nitride as shown in Fig. 2(a). However, when nitriding at 480 °C, the crystallized phase will retain the 1:12 structure but with an obvious increase in the amount of $\alpha\text{-Fe}(\text{V})$ [Fig. 2(b)]. When the compounds, crystallized between 750 and 950 °C, are nitrided, they retain the 1:12 structure with only a small amount of precipitated $\alpha\text{-Fe}(\text{V})$ [Fig. 2(c)]. This precipitation is unavoidable even if the crystallized phase is a single phase, as in $\text{Nd}(\text{Fe}_{0.83}\text{V}_{0.17})_{11}$ [Fig. 2(d)], which is similar to $\text{NdFe}_{11}\text{Ti}$ but different from $\text{Nd}(\text{Fe},\text{Mo})_{12}$. The crystallized $\text{Nd}(\text{Fe},\text{Mo})_{12}$ retains the 1:12 structure even when nitriding at 600 °C without precipitation

FIG. 2. X-ray diffraction patterns of (a) $\text{NdFe}_{10.5}\text{V}_{1.5}$ (crystallized at 750 °C, nitrided at 450 °C), (b) $\text{NdFe}_{10.5}\text{V}_{1.5}$ (crystallized at 750 °C, nitrided at 480 °C), (c) $\text{NdFe}_{10.5}\text{V}_{1.5}$ (crystallized at 850 °C, nitrided at 480 °C), (d) $\text{NdFe}_{10.5}\text{V}_{1.5}$ (crystallized at 850 °C, nitrided at 480 °C), (e) $\text{Nd}(\text{Fe}_{0.83}\text{V}_{0.17})_{11}$ (crystallized at 850 °C, nitrided at 480 °C).

of $\alpha\text{-Fe}(\text{Mo})$. If nitriding at above 600 °C, the $\text{Nd}(\text{Fe},\text{M})_{12}$ compounds will decompose into a mixture of RN and $\alpha\text{-Fe}(\text{M})$, which is generally explained in view of the minimum of total free energy. Introducing nitrogen atoms into the rare earth transition metal compounds will result in stress or strain buildup in the nitrided particles due to lattice dilation. A stable compound suggests that it can withstand higher stress and/or strain, and it will not decompose during nitriding and the nitrides will be stable at higher temperature. This may explain the different nitriding behaviors of Mo, Ti, and V stabilized 1:12 compounds. When crystallizing MA $\text{Nd}(\text{Fe},\text{V})_{12}$ below 750 °C, the 1:12 compound formed is imperfect with many interfaces with the unreacted $\alpha\text{-Fe}(\text{V})$. Upon nitriding at 450 °C, stress is induced inside the 1:12 phase, which cannot be relaxed easily, and when combined with the weak lattice constraint, will result in the phase transformation from 1:12 to 1:7. However, when nitriding at 480 °C, the stress is relaxed and can accelerate the decomposition of 1:12 but does not change its crystal structure.

C. Magnetic properties of MA $\text{Nd}(\text{Fe},\text{M})_{12}\text{N}_x$ compounds

Figure 3 shows the hysteresis loops, for fields of up to 1.5 T (a) and 17 T (b), of $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ after crystallizing at 850 °C for 3 h and nitriding at 480 °C for 3 h. The intrinsic coercivity is 8.8 kOe. It can also be seen that the virgin magnetization curve [Fig. 3(a)] is smooth, which implies no pinning sites in the compounds and its coercivity should be determined by the reverse domain nucleation field. However, on the virgin magnetization curves of MA $\text{NdFe}_{10.5}\text{Mo}_{1.5}\text{N}_x$ and $\text{Sm}_2\text{Fe}_{17}\text{N}_x$ (Ref. 5) compounds, there are jumps at magnetization fields equal to their coercivities, which means that domain wall pinning determines the coercivities in these compounds. This difference originates from the precipitated $\alpha\text{-Fe}(\text{V})$, which generally is located on the surface of $\text{Nd}(\text{Fe},\text{V})_{12}$ particles, and acts as a reverse domain nucleation site reducing the coercivity and the squareness of the demagnetization curve. By controlling the grain size and distribu-

FIG. 3. Hysteresis loops of $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ compounds measured in a field of up to 1.5 T (a) and 17 T (b). For (a) the field scale is multiplied by 6 for clarity.

tion of $\alpha\text{-Fe(V)}$ and $\text{Nd(Fe,V)}_{12}\text{N}_x$ compounds, exchanged coupled remanence enhanced composite magnets could be realized.⁶

IV. CONCLUSION

MA has been successfully used in the preparation of $\text{Nd(Fe,M)}_{12}\text{N}_x$ permanent magnets. Intrinsic coercivity of 8.8

kOe has been obtained for $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$. The stress introduced by nitrogen atoms and the stability of the original compounds control the phase transformation during nitriding. The difference in coercivities for Ti,V,Mo stabilized $\text{Nd(Fe,M)}_{12}\text{N}_x$ and $\text{Sm}_2\text{Fe}_{17}\text{N}_x$ compounds originates from the different phase stability range and the morphology of precipitated $\alpha\text{-Fe(M)}$. It is also suggested that $\text{Nd(Fe,V)}_{12}\text{N}_x$ could be used to produce remanence enhanced composite magnets.

$R\text{Fe}_{12-x}\text{T}_x\text{C}_y$ ($R=\text{Y,Er}$; $T=\text{V,Ti,Mo}$) alloys were prepared by rf induction melting and analyzed using neutron powder diffraction and superconducting quantum interference device (SQUID) measurements. Rietveld analysis of the neutron diffraction data indicates that V, Ti, and Mo atoms all prefer the 8i sites. The refined amount of carbon atoms found in the interstitial sites from neutron diffraction data is significantly less than the nominal carbon content. All samples have the easy direction along the c axis. The Er sublattice couples to the Fe sublattice antiferromagnetically. The average Fe site moments range from 1.3 to 2.8 μ_B . The anisotropies of the crystal structures are found to relate to both the rare earth atoms and the stabilizing transition metal atoms. The SQUID measurements show that all samples have a Curie temperature near 600 K. © 1996 American Institute of Physics. [S0021-8979(96)32108-5]

INTRODUCTION

It is well accepted that the $R\text{Fe}_{12-x}\text{T}_x\text{C}_y$ and $R\text{Fe}_{12-x}\text{T}_x\text{N}_y$ ($R=\text{rare earths}$, $T=\text{Ti,V,Mo}$) compounds are among the most promising candidates for permanent magnet applications,^{1–8} not only for their excellent magnetic properties, but also for their lower ratio of rare earth to transition metal than those of the 2:17 and 3:29 phases. The nitrogen atoms can only be introduced into the $R\text{Fe}_{12-x}\text{T}_x$ compounds by a gas phase reaction. The carbon atoms can be introduced into the $R\text{Fe}_{12-x}\text{T}_x$ compounds either during melting or by gas phase reaction. Up to the present, better magnetic properties have been observed in nitrides,¹ and thus, the nitrides have attracted much more attention.^{1–8} Because of the technical advantage of the melting method, it is very important to study the carbides prepared by melting. Here we report the results of neutron diffraction and magnetic studies of several carbides ($R\text{Fe}_{12-x}\text{T}_x\text{C}_y$ with $R=\text{Y,Er}$; $T=\text{V,Ti,Mo}$) prepared by rf-induction melting.

EXPERIMENT

Four samples of $R\text{Fe}_{12-x}\text{T}_x\text{C}_y$ ($R=\text{Y,Er}$; $T=\text{V,Ti,Mo}$) were prepared by rf induction melting the constituent elements of purity 99.9%–99.995% in a water-cooled copper boat under flowing argon at the Graduate Center for Materials Research, University of Missouri–Rolla. The ingots were annealed at 980 °C for one week. The ingots were then crushed and ground in an acetone bath. Neutron diffraction data were collected at the University of Missouri Research Reactor using the high resolution linear position sensitive detector diffractometer at room temperature on approximately 2 g samples in about 24 h. The neutron wavelength is 1.4783 Å. The data were measured from 5° to 105° in 2θ . The neutron diffraction powder patterns were analyzed by the Rietveld method using the FULLPROF program for multiphase refinements including magnetic structure refinements. The superconducting quantum interference device (SQUID) measurements were performed with a Quantum Design MPMS system.

RESULTS AND DISCUSSION

The refinement results of the powder neutron diffraction data are given in Table I. Based on the refinements, all samples were confirmed to have the tetragonal ThMn_{12} -type structure with space group $I4/mmm$. No second phase was recognized for any sample. The two possible sites that can be occupied by interstitial C atoms are the octahedral $2b$ (0 0 1/2) sites, with two rare-earth neighbors and four transition metal neighbors, or the tetrahedral $8h$ ($\sim 1/4 \sim 1/4$ 0) sites, with one rare-earth neighbor and three transition metal neighbors. However, when we refine the C occupancies on those two sites, the C content is found to be much lower than the nominal C content. As shown in Table I, the nominal C content for the Er–V–Fe–C sample is 0.4/formula unit (f.u.), the refined C content on the $2b$ and $8h$ sites is only 0.032/f.u. The nominal C content for the Er–Ti–Fe–C sample is 0.25/f.u., the refined C content on the $2b$ and $8h$ sites is zero. The largest refined C content is obtained for the Y–Mo–Fe–C sample, but the result (0.18/f.u.) is still significantly lower than the nominal value (0.3/f.u.). Because no second phase was observed, this suggests that some or most of the C atoms have possibly been introduced into the structures substitutionally. That is, the C atoms may go into the transition metal sublattice and the doubly substituted compounds form. Because it is not possible to determine the site occupancies of a doubly substituted compound from neutron diffraction data only,⁹ it is difficult to determine which site(s) the C atoms occupy. However, because no second phase was found, we assume that the T/Fe ratio in the samples is the same as nominal (1.5T/10.5Fe). By using this and the assumption that the rare-earth site is fully occupied, it is easy to determine the final net compositions of the samples (see the Appendix), which are given in Table I (where C^s stands for the substitutional carbon and C^i represents the interstitial carbon). They are found to be in good agreement with the nominal compositions. A special case is for the sample with the nominal formula $\text{YFe}_{10.5}\text{Mo}_{1.5}\text{C}_{0.3}$ for which only 8i sites were observed to contain substituents. Thus it is clear that

^aNominal composition.^bRefined composition.

any substitutional C atoms in this sample occupy the 8*i* sites as Mo atoms do. For the other three samples, multiple site occupancy by C is possible. In fact, because all samples were prepared in a rare-earth rich environment, it is not unreasonable that C atoms occupy some transition metal sites without affecting the phase mix.

Also given in Table I are the ratios of the effective site scattering length/Fe scattering length (*b*_{eff}/*b*_{Fe}). Fe has the largest scattering length among the elements involved in this study. Thus, the greater the reduction of *b*_{eff}/*b*_{Fe} from 1, the greater the substitution. The biggest reductions of *b*_{eff}/*b*_{Fe} are found for the 8*i* site for all samples, which means the V, Ti, and Mo atoms all show a strong affinity for the 8*i* sites in the transition metal sublattice. This affinity is determined by co-

ordination effects. The 8*i* site has only one rare-earth neighbor and 13 transition metal neighbors, indicating that the substituent atoms V, Ti, and Mo avoid bonding to rare earth atoms. The anisotropy of the crystal structures is found to relate to both the rare-earth atoms and the stabilizing transition metal atoms. The substituted Y-Fe-Mo sample is more anisotropic in crystal structure (*c/a*=0.5601) than the substituted Y-Fe-V sample (*c/a*=0.5621) which is, in turn, more anisotropic than the Er-Fe-V sample (*c/a*=0.5632).

The refinements show that all samples have the easy direction along the *c* axis. The average Fe site moments are 1.36 μ_B for the YFe_{10.5}Mo_{1.5}C_{0.3} sample, 1.67 μ_B for the ErFe₁₁TiC_{0.25} sample, 2.43 μ_B for the YFe_{10.5}V_{1.5}C_{0.4} sample, and 2.83 μ_B for the ErFe_{10.5}V_{1.5}C_{0.3} sample. As expected, the Er sublattice was found to couple to the Fe sublattice antiferromagnetically. The Er site moment is smaller in the Er-V-Fe-C sample than in the Er-Ti-Fe-C sample, indicating the antiferromagnetic interaction between the rare earth sublattice and Fe sublattice is weaker in Er-V-Fe-C than in Er-Ti-Fe-C. The heavy rare-earth-Fe compounds usually have Curie temperatures higher than those of the corresponding light rare-earth-Fe compounds, but the antiferromagnetic exchange between the heavy rare earth sublattice and Fe sublattice is a major deficiency of the heavy rare-earth-Fe compounds. This study suggests that the antiferromagnetic exchange in heavy rare-earth-Fe 1:12 compounds can be reduced by changing the composition of the compound. It is also noted that both V-substituted samples have larger site moments than the Ti and Mo samples do. This suggests that more attention should be paid to V-substituted compounds in the future.

FIG. 1. SQUID magnetization curve for ErFe_{10.5}V_{1.5}C_{0.4}.

It was reported that the easy direction of the $\text{ErFe}_{10}\text{V}_2\text{N}_x$ compound at 10 K is within the ab plane but along the c axis at 300 K.¹ Our SQUID measurement shows that this change of easy direction for $\text{ErFe}_{10.5}\text{V}_{1.5}\text{C}_{0.4}$ happens at around 45 K (Fig. 1). The SQUID measurements also show that all samples have a Curie temperature around 600 K (Table I). The Curie temperatures of the carbides, as expected, are higher than those of the uncarbonated compounds but much lower than those of the corresponding nitrides.¹

CONCLUSIONS

All the V, Ti, and Mo atoms prefer the $8i$ sites. The interstitial carbon atoms were found in the $2b$ sites. However, the refined amount of carbon atoms found in the interstitial sites from neutron diffraction data is significantly less than the nominal carbon content. Calculation of the net scattering amplitudes on each site supports this assumption. All samples have the easy direction along the c axis. The Er sublattice was found to couple to the Fe sublattice antiferromagnetically. The average Fe site moments range from 1.3 to $2.8 \mu_B$. The anisotropy of the crystal structures are found to relate to both the rare-earth atoms and the stabilizing transition metal atoms. All samples have a Curie temperature near 600 K.

APPENDIX: DETERMINATION OF THE SUBSTITUENT CONTENTS IN THE T+C DOUBLE SUBSTITUTED 1:12 PHASE, $\text{RFe}_{12-x-y}\text{T}_x\text{C}_y$

For the T+C doubly substituted 1:12 phase, $\text{RFe}_{12-x-y}\text{T}_x\text{C}_y$, the effective scattering lengths of the three iron sites are

$$b_{\text{eff}1} = x_1 b_T + y_1 b_C + (0.25 - x_1 - y_1) b_{\text{Fe}}, \quad (\text{A1})$$

$$b_{\text{eff}2} = x_2 b_T + y_2 b_C + (0.25 - x_2 - y_2) b_{\text{Fe}}, \quad (\text{A2})$$

$$b_{\text{eff}3} = x_3 b_T + y_3 b_C + (0.25 - x_3 - y_3) b_{\text{Fe}}, \quad (\text{A3})$$

where $b_{\text{eff}1}$, $b_{\text{eff}2}$, and $b_{\text{eff}3}$ are refined effective scattering lengths on the three Fe sites, b_T , b_C , and b_{Fe} are the scattering lengths of transition metal, carbon, and Fe, respectively,

x_i ($i=1,2,3$) are transition metal site occupancies, and y_i ($i=1,2,3$) are C sites occupancies. Taking Eqs. (A1)+(A2)+(A3) we get

$$b_{\text{eff}} = x b_T + y b_C + (0.75 - x - y) b_{\text{Fe}}, \quad (\text{A4})$$

where b_{eff} is the total effective scattering length of the three Fe sites, x is the total occupancy of transition metal, y is the total occupancy of carbon, and

$$b_{\text{eff}} = b_{\text{eff}1} + b_{\text{eff}2} + b_{\text{eff}3},$$

$$x = x_1 + x_2 + x_3,$$

$$y = y_1 + y_2 + y_3.$$

To determine x and y , we need one more independent equation. Here we assume that the T/Fe ratio in the samples is the nominal one (1.5T/10.5Fe), that is

$$x/(0.75 - x - y) = (W_T/M_T)(W_{\text{Fe}}/M_{\text{Fe}}), \quad (\text{A5})$$

where W_T and W_{Fe} are the starting weights of transition metals and Fe, M_T , and M_{Fe} are the atomic weights of transition metals and Fe, respectively.

By solving the independent Eqs. (A4) and (A5), x and y can be determined.

Structure and magnetic properties of mechanical alloyed Nd-Fe-Ti compounds and their nitrides

Zhi-qiang Jin, X. K. Sun, W. Liu, X. G. Zhao, Q. F. Xiao, Y. C. Sui, Z. D. Zhang, and Zhigang Wang

Institute of Metal Research, Academia Sinica, Shenyang 110015, People's Republic of China

The Nd-Fe-Ti intermetallic compounds with a ThMn₁₂ structure have been successfully prepared by mechanical alloying and then annealed. It has been found that the phase of the hexagonal TbCu₇ structure is formed in Nd₈Fe₈₄Ti₈ mechanical alloy powders annealed at temperatures ranging from 650 to 850 °C. With an increase in the annealing temperature T_a , the metastable TbCu₇ structure transforms into a ThMn₁₂ structure at $T_a=900$ °C. Consequently, the Curie temperature increases from 180 °C of TbCu₇ structure at $T_a=650$ to 300 °C of ThMn₁₂ structure at $T_a=1050$ °C. In the series of Nd_xFe_{92-x}Ti₈ annealed at 960 °C for 30 min, it has been observed that the ThMn₁₂ structure exists only over the range of compositions of $5 \leq x < 11$, and the structure of the type Th₂Zn₁₇ is formed for $x \geq 11$. All the compounds are nitrated at 400 °C for 15 h, and the Curie temperatures are raised from 400 to 450 °C. The Nd₉Fe₈₃Ti₈ powder, annealed at 960 °C for 30 min, and nitrated at 400 °C for 15 h, has a coercivity $H_c=2.3$ kOe. The low coercivity perhaps mainly results from an excessive growth of α -Fe grains due to the high annealing temperature necessary for forming the hard magnetic phase Nd(Fe,Ti)₁₂N₈. © 1996 American Institute of Physics. [S0021-8979(96)32208-1]

I. INTRODUCTION

As far as our knowledge is concerned, the magnets prepared by the mechanical alloying (MA) technique have high coercivity compared with those prepared by traditional methods.^{1,2} It is well known that Nd(Fe,TM)₁₂N₈ compounds (TM=Ti,V,Mo) with a ThMn₁₂ structure have excellent intrinsic magnetic properties which are comparable to those of Nd₂Fe₁₄B compounds.³ In addition, this kind of compound has the lowest relative content of rare earth (without relatively scarce Sm among them) compared to all the other previously discovered rare earth permanent magnet (REPM) compounds. In this regard, they are potentially favorable for the low cost production of REPM. Therefore, the Nd(Fe,TM)₁₂N₈ compounds with interstitial nitrogen have been thought to be a new perspective candidate of REPM. Unfortunately, no reports concerning MA synthesis of the Nd(Fe,Ti)₁₂ compound and its counterpart of nitride (with ThMn₁₂ structure) have been found so far, although other rare earth-transition metal compounds such as SmCo₅,⁴ Sm₂Fe₁₇N_x,¹ Sm₅Fe₁₇,² and Nd₂Fe₁₄B⁵ have been successfully prepared by MA and subsequent heat treatment. Thus, the facts mentioned above urge us to study the preparation of Nd(Fe,Ti)₁₂ compounds and their nitrides by using the MA technique. Primary results of the research are briefly reported here; a somewhat detailed report will be published elsewhere.

II. EXPERIMENT

A series of Nd_xFe_{92-x}Ti₈ ($x=4-11$) specimens was prepared by MA under an argon atmosphere for 5 h of the mixed powders comprising the starting metals with purities of 99.6%, 99%, 99% for Fe, Ti, and Nd elements, respectively. Annealing treatment of the MA powder specimens was carried out at 600–1050 °C for 5–60 min in vacuum of $(2-3) \times 10^{-5}$ Torr. Nitrogenation of the annealed powder

specimens was performed at 400 °C for 2–40 h in a pure nitrogen atmosphere. X-ray diffraction (XRD) analysis of powder specimens was conducted using Cu K_α radiation with a Rigaku D/Max-rA diffractometer equipped with a graphite crystal monochromator. An initial ac susceptibility measurement was applied to determine the Curie temperature and to make a preliminary estimate of the possible magnetic phases in the specimens under study. The magnetically isotropic magnets made of the powders embedded in epoxy resin were used for the magnetic measurements at room temperature. The magnetic measurements were performed using a pulsed magnetometer in fields up to 8 T.

III. RESULTS AND DISCUSSION

XRD study has been applied to establish the proper milling times of mechanical alloying. It has been found that the characteristic peaks of Nd and Ti have been completely submerged into the background after 5 h, while retaining the prominent characteristic peaks of α -Fe up to milling for 30 h, which implies an extreme difficulty in getting the amorphous structure of iron. Prolonging the time of milling only makes the average particle dimension of the powders approach a stable limit. Thus, the milling time of 5 h has been reasonably selected. Figure 1 represents the XRD patterns of Nd₈Fe₈₄Ti₈ powder at different annealing temperatures for 30 min. The magnetic phase identification of the specimens was performed by XRD as shown in Fig. 1, in combination with a thermomagnetic analysis. It has been found that none of the magnetic phases is observed in the specimen annealed at 600 °C and the phase of the TbCu₇ structure is formed at $T_a=700$ °C. Furthermore, it is observed that the transformation of Nd(Fe,Ti)₇, of which the Curie temperature T_C increases from 180 °C at $T_a=700$ to 250 °C at $T_a=800$ °C, into Nd(Fe,Ti)₁₂ (with the ThMn₁₂ structure) occurs at 900 °C [cf. Fig. 1(c)]. The Curie temperature of the latter is 270 °C. It may be thought that the transformation is essen-

FIG. 1. X-ray diffraction patterns of $\text{Nd}_8\text{Fe}_{84}\text{Ti}_8$ powders of different annealed temperatures for 30 min: (a) 700 °C, (b) 850 °C, (c) 900 °C, (d) 960 °C, and (e) 1050 °C.

tially complete at $T_a=960$ °C for 30 min [cf. Figs. 1(d) and 1(e)]. The experimental results indicate that the Curie temperature T_C continuously increases with increasing T_a and $T_C=300$ °C is reached for annealing at $T_a=1050$ °C. The transformation may result from the high diffusion activity of elements and the evaporation of rare earth elements. In the MA preparation of $\text{Nd}(\text{Fe,Ti})_{12}$, a moderately high annealing temperature is needed so that the solid state reaction to form the 1:12 phase can be completed. The experiment of XRD and thermomagnetic analysis show that excessively prolonging annealed time does not essentially influence the transformation between the 1:7 and 1:12 phases. This fact implies that the annealing temperature rather than the time is critical for the transformation from 1:7 to 1:12.

XRD patterns for various contents of Nd in $\text{Nd}_x\text{Fe}_{92-x}\text{Ti}_8$ powders prepared by MA and annealed at 960 °C for 30 min are shown in Fig. 2. It can be seen that the alloy composition, to a great extent, determines the phase component of the alloy. The $\text{Nd}(\text{Fe,Ti})_{12}$ compound, with a Curie temperature of about 280 °C, and which slightly depends on the composition, is formed for $5 \leq x \leq 10$, with the existence of $\alpha\text{-Fe}$, Fe_2Ti , and rare earth oxides. A near single phase of $\text{Nd}(\text{Fe,Ti})_{12}$ is obtained for $x=10$, where a small amount of rare earth oxides is included. With increasing Nd content, the amounts of $\alpha\text{-Fe}$ and Fe_2Ti decrease, and the phase with the $\text{Th}_2\text{Zn}_{17}$ structure, where the Curie temperature is about 140 °C, is formed for $x \geq 11$. Further increasing the Nd content once again results in the formation of Fe_2Ti . Moreover, Nd_2O_3 cannot be avoided in all the compositions of the specimens. Figure 3 shows the dependence of coercivity on nitrided time at 400 °C for $\text{Nd}_8\text{Fe}_{84}\text{Ti}_8$ specimens annealed at 960 °C for 30 min and at 950 °C for 20 min, respectively. It can be seen that the former has a better coercivity than the latter. This result indicates that a properly high temperature and slightly long annealing time are beneficial to the formation of $\text{Nd}(\text{Fe,Ti})_{12}\text{N}_8$. Figure 3 reveals that the coercivity first increases and then decreases with

FIG. 2. X-ray diffraction patterns for mechanically alloyed $\text{Nd}_x\text{Fe}_{92-x}\text{Ti}_8$ annealed at 960 °C for 30 min.

prolonged nitrided time. Upon annealing at 960 °C for 30 min and nitriding at 400 °C for 18 h, the magnet has a coercivity $iH_c=2.3$ kOe. It should be pointed out that the Curie temperature of $\text{Nd}(\text{Fe,Ti})_{12}$ exhibits a notable increase after nitrogenation. It has been found that the Curie temperature is 280 °C for the annealed specimen and 450 °C when the specimen is subsequently nitrided for 15 h. For 2 h nitriding, the two Curie temperatures were found to correspond to two magnetic phases— $\text{Nd}(\text{Fe,Ti})_{12}$ and its nitride—and this im-

FIG. 3. Dependence of coercivity on nitrided time for $\text{Nd}_8\text{Fe}_{84}\text{Ti}_8$ specimens annealed at 960 °C for 30 min and at 950 °C for 20 min, respectively, and nitrided at 400 °C.

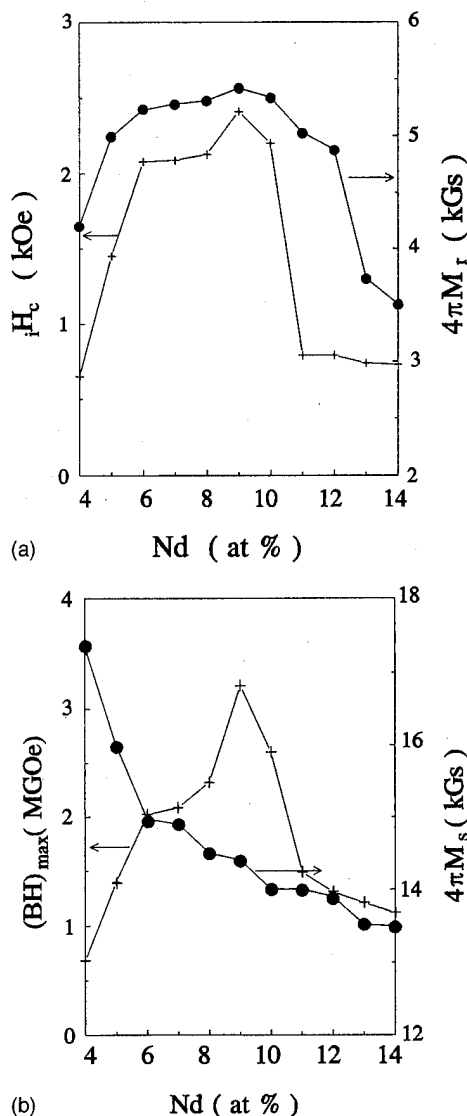

FIG. 4. Dependence of magnetic properties on Nd content for $\text{Nd}_x\text{Fe}_{92-x}\text{Ti}_8$ specimens annealed at 960 °C for 30 min and nitrided at 400 °C for 15 h: (a) H_c and $4\pi M_r$, (b) $(BH)_{\max}$, and $4\pi M_s$.

plies an imperfect nitriding process. Thus, $\text{Nd}(\text{Fe,Ti})_{12}$ and $\text{Nd}(\text{Fe,Ti})_{12}\text{N}_\delta$ coexist. In addition, it should be noted that too high a nitriding temperature (>450 °C) results in a decomposition of the studied compound and thus the magnetic properties are degraded.

The dependence of the magnetic properties in the series of $\text{Nd}_x\text{Fe}_{92-x}\text{Ti}_8$ annealed at 960 °C for 30 min and nitrided at 400 °C for 15 h on the composition is shown in Fig. 4. It is observed that the coercivity H_c , the remanence $4\pi M_r$, and the maximum magnetic energy product $(BH)_{\max}$ of the nitrides first increase with increasing Nd content. The maximum values of $H_c=2.3$ kOe, $4\pi M_r=5.8$ kGs, and $(BH)_{\max}=3.2$ MG Oe, respectively, are obtained at about $x=9$. It is obvious that the excessive content of neodymium in the specimens with $x>9$, is not favorable for the magnetic hardening of the magnets. A possible reason for this is that the excess of neodymium destroys the perfectness of the structure of the hard magnetic 1:12 phase, which is identified by broadening of the peaks of the XRD pattern for $x=10$, and perhaps, it is a forerunner of the transformation from 1:12 to 2:17, followed by the occurrence of the transformation for $x>10$. In contrast, the saturation magnetization decreases monotonously with increasing x values. Although the incompatible variation of the remanence with the saturation magnetization is very interesting, it is difficult to clearly explain this phenomenon. It should be noted that an unusually low coercivity is attained and this value is expected to be higher due to the high uniaxial magnetocrystalline anisotropy field H_A of $\text{Nd}(\text{Fe,Ti})_{12}\text{N}_\delta$ ($H_A \approx 80$ kOe at room temperature).³ The low coercivity perhaps mainly results from an excessive growth of α -Fe grains due to the high annealing temperature necessary for forming the hard magnetic phase $\text{Nd}(\text{Fe,Ti})_{12}\text{N}_\delta$. Therefore, the remanence enhancement could not be achieved by the presence of α -Fe in the magnets.

High coercivity of melt-spun $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ compound

Jun-Xian Zhang, Zhao-Hua Cheng, and Bao-Gen Shen

State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 100080, People's Republic of China

The magnetic hardening of melt-spun $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ was studied and the coercivity of 4.6 kOe for $\text{Sm}_2\text{Fe}_{17}\text{C}_{1.5}$ alloys was reported a few years ago. Recently, we have succeeded in preparing single-phase compounds of $\text{Sm}_2(\text{Fe}, \text{M})_{17}\text{C}_x$ ($\text{M}=\text{Ga}, \text{Al}, \text{or Si}$) with high carbon concentration by arc melting. It was found that the substitution of Ga or Al not only facilitated the formation of high carbon concentration rare-earth iron compounds with a 2:17-type structure, but also was very effective in raising the value of the anisotropy field. For example, the sample of $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ has a saturation magnetization of 110.2 emu/g, a Curie temperature of 576 K, and an anisotropy field of 111 kOe. It is known that melt spinning is an effective means to obtain high coercivity of magnetically hard materials. In this work, the hard magnetic properties of melt-spun $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ alloys were investigated. It was found that the value of coercivity depends strongly on the quenching rates and an optimum coercivity of 9.4 kOe was obtained at the quenching rate of 20 m/s. X-ray diffraction patterns indicate that the as-quenched ribbons have a phase of the $\text{Th}_2\text{Zn}_{17}$ -type structure. The high coercivity of these as-quenched ribbons originates from the excellent intrinsic magnetic properties of $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$. It can be concluded that the substitution of Al is very effective in raising the coercivity of melt-spun $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ ribbons. © 1996 American Institute of Physics. I. INTRODUCTION

The $\text{Sm}_2\text{Fe}_{17}\text{N}_x$ and $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ compounds with higher nitrogen or carbon concentrations are promising candidates for permanent magnets owing to their excellent intrinsic hard magnetic properties.^{1,2} However, a serious drawback of the nitrides or carbides prepared by the gas-solid reaction is their poor high-temperature stability. These compounds decompose into the equilibrium phase rare-earth nitrides (carbides) and $\alpha\text{-Fe}$ upon heating to 600–700 °C. This restricts the actual application for the sintered permanent magnet. Recently, we have studied the effect of various elemental substitutions for Fe on the formation, structure, and magnetic properties of the $\text{R}_2\text{Fe}_{17}\text{C}_x$ alloys and found that the high-carbon $\text{R}_2\text{Fe}_{17}\text{C}_x$ compounds containing Ga, Al, or Si, etc., exhibited a high thermal stability. The 2:17-type carbides containing Ga, Al, or Si, etc., can be directly formed by arc melting. It was found that the substitution of Ga, Al, or Si can not only help the formation of 2:17-type rare-earth iron compounds with high carbon concentration, but also is very effective in raising the value of the anisotropy field. We have reported some results of high-carbon $\text{Sm}(\text{Fe}, \text{M})_{17}\text{C}_x$ ($\text{M}=\text{Ga}, \text{Al}, \text{or Si}$) compounds.^{3–6} It is known that melt-spinning is an effective means to obtain high coercivity of magnetically hard materials. In this paper, the hard magnetic properties of melt-spun $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ alloys were investigated.

II. EXPERIMENT

Fe and C were first melted together into Fe–C alloys and then Fe, Sm, Al, and Fe–C alloys were melted by arc melting in an argon atmosphere of high purity. The elements used were at least 99.9% pure. An excess of 5% Sm was added to compensate for the evaporation during melting and melt-spinning steps. The ingot alloys were melted at least four times to ensure homogeneity. The ingots were melt-spun in a high-purity argon atmosphere using a copper quenching

wheel rotating at a surface velocity V_s between 0 and 40 m/s. The ribbons were about 1 mm wide and 20–30 μm thick. The phase composition and structure were investigated with a Cu $K\alpha$ x-ray diffractometer. The hysteresis loops were measured by an extracting sample magnetometer with a magnetic field up to 70 kOe.

III. RESULTS AND DISCUSSION

In our reported work,^{6,8} the formation and magnetic properties of $\text{Sm}_2\text{Fe}_{17-x}\text{Al}_x\text{C}_y$ compounds were studied. It was found that the sample of $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ has excellent intrinsic magnetic properties, such as a saturation magnetization of 110.2 emu/g, Curie temperature of 576 K, and anisotropy field of 110 kOe. Thus, this sample was selected to study the effect of melt-spinning on the coercivity. X-ray diffraction experiments indicate that $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ alloys have a rhombohedral $\text{Th}_2\text{Zn}_{17}$ -type structure. In order to obtain a high coercivity, we prepared ribbons at various quenching rates. For example, Fig. 1 shows the hysteresis loop for as-quenched $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ ribbon by direct melt-spinning at 20 m/s. For comparison the hysteresis loop for as-quenched $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2\text{C}_{1.5}$ ribbon by optimum melt-spinning at 30 m/s is also shown in Fig. 1. The coercivity of $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ ribbons as a function of quenching rates is plotted in Fig. 2. It can be seen that the value of coercivity depends strongly on the quenching rates. The coercivity is found to have a maximum value of 9.4 kOe when the quenching rate is about 20 m/s and is reduced quickly when quenching rate is either slower or faster than optimum, falling to less than 500 Oe at 40 m/s.

The x-ray diffraction patterns of the as-quenched $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ ribbons show that the sample for $V_s=15, 20,$ and 25 m/s can be indexed to the $\text{Th}_2\text{Zn}_{17}$ -type structure, indicating that the ribbons are almost entirely comprised of hard magnetic phase, a few percent of $\alpha\text{-Fe}$ was present as

FIG. 1. Hysteresis loops for $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ ribbon with a quenching rate of 20 m/s and $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2\text{C}_{1.5}$ ribbon with a quenching rate of 30 m/s.

well. Because the magnetization in the grains comprised of the soft magnetic phase is easily reversed under an external small opposite magnetic field, it induces a cascade of demagnetization processes within adjacent grains. For these samples, the value of coercivity is lower. In the

FIG. 2. The coercivity of $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ ribbons as a function of quenching rates.

TABLE I. The anisotropy field and coercivity of compounds.

Compounds	H_a (kOe)	H_c (kOe)	$H_c : H_a$
$\text{Sm}_2\text{Fe}_{17}\text{C}_{1.5}$ ^a	53	4.6	1:10
$\text{Sm}_2\text{Fe}_{14}\text{Ga}_2\text{C}_{1.5}$ ^b	120	16	1:10
$\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$	111	9.4	1:10

^aFrom Ref. 7.

^bFrom Ref. 9.

$\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ ribbon for $V_s=40$ m/s an amorphous phase starts to form and only a small amount of the $\text{Th}_2\text{Zn}_{17}$ phase remains. The formation of the amorphous phase and the very fine grains of the $\text{Th}_2\text{Zn}_{17}$ phase is consistent with the low coercivity.

Early studies of the $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ alloys showed the anisotropy field is 53 kOe for $\text{Sm}_2\text{Fe}_{17}\text{C}_{1.5}$, and the largest coercivity 4.6 kOe for the quenched sample.⁷ For comparison the anisotropy field and the largest coercivity for quenched alloys of $\text{Sm}_2\text{Fe}_{17}\text{C}_{1.5}$, $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2\text{C}_{1.5}$,⁹ and $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ compounds is listed in Table I. The coercivity reaches about 1/10 of the anisotropy field for these compounds. The high coercivity of these as-quenched ribbons originates from the excellent intrinsic magnetic properties of $\text{Sm}_2\text{Fe}_{17}\text{C}_{1.5}$, $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2\text{C}_{1.5}$, and $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$, respectively.

In conclusion, the hard magnetic properties of the $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ compounds have been studied by melt-spinning. Coercivity of 9.4 kOe was obtained. It can be concluded that the substitution of Al is very effective in raising the coercivity of melt-spun $\text{Sm}_2\text{Fe}_{15}\text{Al}_2\text{C}_{1.5}$ ribbons.

In order to study the location of hydrogen atoms and the effects of their insertion into R_2Fe_{17} , spin-echo NMR experiments have been carried out on the hexagonal $Y_2Fe_{17}H_x$ ($x=0, 3.0, 4.7$), rhombohedral $Sm_2Fe_{17}H_x$ ($x=0, 1.7, 5.7$), and mixed-phase $Gd_2Fe_{17}H_x$ ($x=0, 2.3, 5.8$) compounds. 1H and ^{89}Y spectra obtained from $Y_2Fe_{17}H_x$ clearly demonstrate that the hydrogenation process is reversible upon vacuum annealing. For both $Y_2Fe_{17}H_x$ and $Sm_2Fe_{17}H_x$, the 1H spectra show two broad peaks; the peaks are tentatively assigned to H atoms in the tetrahedral and octahedral interstitial sites, and a hydrogen filling scheme is proposed. For $Gd_2Fe_{17}H_x$, a single broad 1H peak near 70 MHz is observed; application of an external magnetic field indicates that the hyperfine field has the same direction as the net magnetization. © 1996 American Institute of Physics. [S0021-8979(96)32408-4]

I. INTRODUCTION

Since the discovery that Sm_2Fe_{17} can absorb a large amount of nitrogen which substantially improves the magnetic properties,¹ much attention has been focused on the R_2Fe_{17} nitrides, carbides, and hydrides, where R is a rare earth atom except lanthanum. In order to understand the nature of the gas phase modification, it is important to determine where these interstitial atoms are located and how they affect the local magnetic properties. So far, several techniques, such as x-ray absorption fine structure (XAFS),² neutron diffraction (ND),³⁻⁵ Mössbauer effect (ME),^{6,7} as well as nuclear magnetic resonance (NMR),⁸⁻¹⁰ have been utilized to study the properties on an atomic scale. Among these techniques, NMR has the advantage of providing a direct measurement for several specific local environments. For example, in the $Y_2Fe_{17}H_x$ hydride system, 1H and ^{89}Y are excellent NMR probes since they are 100% abundant and have a spin of 1/2. Although it is not as favorable as 1H and ^{89}Y , the weak ^{57}Fe NMR signal can be observed in this system when it is not overlapped by the stronger ^{89}Y signal. Reviewing previous work, it is generally accepted that nitrogen and carbon occupy principally the octahedral sites (6h and 9e for the hexagonal and rhombohedral structures, respectively); hydrogen occupies the octahedral sites exclusively until the H content reaches three H atoms per formula unit, and then goes into the tetrahedral interstitial sites (12i and 18g for the hexagonal and rhombohedral structures, respectively).¹¹ Both nitrogen and carbon have a strong influence on the ^{89}Y hyperfine field,^{8,9} whereas it has been reported that hydrogen does not have a significant effect.⁸ In this work, spin-echo NMR spectra are presented for the $Y_2Fe_{17}H_x$ ($x=0, 3.0$, and 4.7), $Sm_2Fe_{17}H_x$ ($x=0, 1.7$, and 5.7), and $Gd_2Fe_{17}H_x$ ($x=0, 2.3$, and 5.8) hydride systems. Assignments are made for the 1H , ^{89}Y , ^{155}Gd , and ^{157}Gd resonance peaks and a filling scheme for the hydrogen occupation is proposed.

II. EXPERIMENTAL PROCEDURE

The Y_2Fe_{17} and Gd_2Fe_{17} parent ingots were fabricated by arc melting, using Fe, Y, and Gd with a purity of 99.95%,

followed by annealing at 950 °C in vacuum for seven days. The polycrystalline ingots were ground into powders with the particle sizes ranging from 25 to 32 μm . The Sm_2Fe_{17} parent sample was chemically synthesized with the particle sizes ranging from 3 to 5 μm .¹² The structures of the powders were analyzed by Cu $K\alpha$ x-ray diffraction. R_2Fe_{17} compounds are characterized by either the Th_2Ni_{17} -like hexagonal or Th_2Zn_{17} -like rhombohedral structure, or perhaps, a mixed phase of both structures. Both structures can be indexed on hexagonal cells; the difference between the two structures is the stacking sequence along the c direction. Hydrogen was loaded at temperatures near 200 °C and pressures of 3–5 atm. The H content was determined by measuring the pressure decrease during the hydrogenation.

The spin-echo NMR spectra were obtained at both liquid helium and liquid nitrogen temperatures, in zero external magnetic field, using a phase-coherent pulse spectrometer. More detailed methodology of NMR in magnetically ordered materials is available elsewhere.¹³

III. RESULTS AND DISCUSSION

The x-ray diffraction powder patterns for the Y_2Fe_{17} , Sm_2Fe_{17} , and Gd_2Fe_{17} parent samples are shown in Fig. 1. Since the R_2Fe_{17} compounds may crystallize in a hexagonal, rhombohedral, or mixed-phase structure, it is necessary to estimate the phase composition by looking at the characteristic peaks for each phase, i.e., the (203) hexagonal peak for $2\theta \approx 41^\circ$ and the (024) rhombohedral peak for $2\theta \approx 38^\circ$. It can be seen in Fig. 1 that Y_2Fe_{17} is predominately in the hexagonal phase with a trace amount of the rhombohedral phase; Sm_2Fe_{17} is entirely in the rhombohedral phase; and Gd_2Fe_{17} is in a mixed phase. Also, the x-ray results for all of these parent samples show the absence of bcc α -Fe. The hydrided samples of these compounds retain the same structures as the parent samples, but with a small volume expansion. All of

FIG. 1. X-ray diffraction powder patterns for (a) hexagonal Y_2Fe_{17} , (b) rhombohedral $\text{Sm}_2\text{Fe}_{17}$, and (c) mixed-phase $\text{Gd}_2\text{Fe}_{17}$, which are the parent samples for the corresponding hydrides.

the hydrides show the basal-plane anisotropy.¹¹ Previous ^{89}Y NMR studies^{9,10} on Y_2Fe_{17} and its nitrides show that the hyperfine fields for the hexagonal (2b,2d) and the rhombohedral (6c) Y sites are so similar that phase disordering is not a problem in the analysis of the spectra.

The spin-echo NMR spectra of ^{89}Y and ^1H for $\text{Y}_2\text{Fe}_{17}\text{H}_x$ ($x=0, 3.0$, and 4.7) at 4.2 K are shown in Figs. 2 and 3, respectively. When Y_2Fe_{17} is hydrogenated, the center of gravity of the ^{89}Y peak shifts down by approximately 4 MHz [Figs. 2(b) and 2(c)], which is larger than the shift reported elsewhere.⁸ The ^{89}Y peak positions and shape vary somewhat with H content, i.e., the nonsymmetric peak for $\text{Y}_2\text{Fe}_{17}\text{H}_{3.0}$ with a pronounced "shoulder" on the high-frequency side, has its strongest intensity at 38.0 MHz , whereas the peak for $\text{Y}_2\text{Fe}_{17}\text{H}_{4.7}$, with less asymmetry, has its strongest intensity at 38.8 MHz . No ^{89}Y satellite peaks are observed with hydrogenation. This is in contrast to the behavior for $\text{Y}_2\text{Fe}_{17}\text{N}_x$ which shows satellite peaks for Y atoms with one, two, and three N atoms as nearest neighbors.^{8,9} In addition, the two

FIG. 2. Spin-echo NMR spectra of ^{89}Y at 4.2 K for (a) Y_2Fe_{17} , (b) $\text{Y}_2\text{Fe}_{17}\text{H}_{3.0}$, (c) $\text{Y}_2\text{Fe}_{17}\text{H}_{4.7}$, and (d) $\text{Y}_2\text{Fe}_{17}\text{H}_{3.0}$ which was annealed at 150°C for 3 h .

FIG. 3. Spin-echo NMR spectra of ^1H at 4.2 K for (a) $\text{Y}_2\text{Fe}_{17}\text{H}_{3.0}$ and (b) $\text{Y}_2\text{Fe}_{17}\text{H}_{4.7}$.

new peaks which appear at 47.1 and 63.0 MHz have intensities that depend on the H content (Fig. 3). When the $\text{Y}_2\text{Fe}_{17}\text{H}_{3.0}$ sample was annealed in vacuum at 150°C for 3 h , the peaks at 47.1 and 63.0 MHz disappeared, and the ^{89}Y peak shifted back to 42.2 MHz with some residual broadening. The NMR results demonstrate that the hydrogenation process is reversible. Based on these observations, it is reasonable to assign the 47.1 and 63.0 MHz peaks to ^1H .

In contrast to Y_2Fe_{17} , $\text{Sm}_2\text{Fe}_{17}$ is magnetically more anisotropic and harder. Consequently, the NMR enhancement factor for this compound is lower and, correspondingly, a larger radio frequency excitation field is required to observe the spin-echo. Figure 4 shows the NMR spectra obtained from $\text{Sm}_2\text{Fe}_{17}\text{H}_x$ ($x=1.7$, and 5.7) at 1.3 and 77 K . The four vertical bars indicate the hyperfine field values obtained from ME results for the four Fe sites.⁶ The NMR spectrum obtained from the parent $\text{Sm}_2\text{Fe}_{17}$ sample reveals two well-resolved but extremely weak ^{57}Fe peaks at 38.8 and 50.0 MHz . Therefore, in the spectra presented in Fig. 4, the con-

FIG. 4. Spin-echo NMR spectra of ^1H at 1.3 K for (a) $\text{Sm}_2\text{Fe}_{17}\text{H}_{1.7}$, (b) $\text{Sm}_2\text{Fe}_{17}\text{H}_{5.7}$, and at 77 K for (c) $\text{Sm}_2\text{Fe}_{17}\text{H}_{5.7}$. The vertical bars indicate the positions of the hyperfine fields for the four Fe sites in $\text{Sm}_2\text{Fe}_{17}$ (Ref. 6).

tributions from ^{57}Fe in the 2:17 phase are negligible. As shown in Fig. 4, the $\text{Sm}_2\text{Fe}_{17}\text{H}_x$ spectra are characterized by two broad lines at 40.5 and 58.5 MHz, with a small peak at 46.7 MHz. In order to make assignments for these peaks, the corresponding spin-lattice relaxation times were measured. It was found that the spin-lattice relaxation times for the 40.5 and 58.5 MHz peaks were of the same order (1 s); however, that for the 46.7 MHz peak was much shorter (0.01 s). Therefore, the peaks at 40.5 and 58.5 MHz were assigned to ^1H , and the peak at 46.7 MHz was assigned to ^{57}Fe from the small amount of bcc $\alpha\text{-Fe}$ precipitation which occurred during hydrogenation, and was not detected by x-ray diffraction. The spectrum obtained from $\text{Sm}_2\text{Fe}_{17}\text{H}_{5.5}$ at 77 K [Fig. 4(c)] confirmed that the 40.5 and 58.5 MHz peaks are only from ^1H since the ^{57}Fe signal is too weak to be seen at liquid nitrogen temperature.

The assignment of the two ^1H peaks for $\text{Sm}_2\text{Fe}_{17}$ and Y_2Fe_{17} in terms of the hydrogen location is not definite. For the H atoms, a strong dipolar field is indicated from muon spin resonance (μSR).¹⁴ The octahedral site is not a site of unique magnetic symmetry. If it was, the two ^1H peaks that were observed here could arise from the octahedral site H atoms with a splitting caused by the dipolar interaction when the magnetization lies in the basal plane. In this case, the contribution from the tetrahedral sites remains to be observed. Another possible assignment is that the two ^1H peaks are due to the H atoms in these two different sites. A previous ND study reports that both the octahedral and tetrahedral sites are occupied by hydrogen.⁷ In terms of the nearest neighbors, a H atom in an octahedral site is surrounded by two rare-earth atoms and four iron atoms, while a H atom in a tetrahedral site is surrounded by two rare-earth atoms and two iron atoms. A simple calculation shows that the volume ratio V_o/V_t for these two sites is 8/3, where V_o is the volume for the octahedral site and V_t is the volume for the tetrahedral site. Therefore, the insertion of a H atom into the octahedral site will be easier since it produces less lattice strain. The NMR results did show the preferential occupancy as indicated by the higher frequency peaks in the ^1H spectra. Based on this assumption, the low frequency peaks (47.1 MHz for $\text{Y}_2\text{Fe}_{17}\text{H}_x$ and 40.5 MHz for $\text{Sm}_2\text{Fe}_{17}\text{H}_x$) were assigned to H atoms in the tetrahedral sites, and the high frequency peaks (63.0 MHz for $\text{Y}_2\text{Fe}_{17}\text{H}_x$ and 58.5 MHz for $\text{Sm}_2\text{Fe}_{17}\text{H}_x$) to H atoms in the octahedral sites. If this assignment is correct, there is clearly a non-negligible occupancy of hydrogen in the tetrahedral sites for $\text{Y}_2\text{Fe}_{17}\text{H}_{3.0}$ [Fig. 3(a)], and even for low H content sample $\text{Sm}_2\text{Fe}_{17}\text{H}_{1.7}$ [Fig. 4(a)]. These results suggest that a filling of both interstitial sites occurs as hydrogen is added to the sample, even though the H atom has the preferential occupancy to the octahedral sites.

The situation for the mixed-phase $\text{Gd}_2\text{Fe}_{17}$ sample is quite complicated. There are three distinct Gd sites, two for the hexagonal (2b and 2d) and one for the rhombohedral (6c), to take into account. Furthermore, Gd has two isotopes, ^{155}Gd and ^{157}Gd , and a large magnetic moment which interacts strongly with Fe. All of these factors make the analysis of the ^{155}Gd and ^{157}Gd very difficult. Fortunately, the spectra for ^1H are more straightforward. Figure 5 shows NMR spectra observed for $\text{Gd}_2\text{Fe}_{17}\text{H}_x$ ($x=0, 2.3$, and 5.8) at

FIG. 5. Spin-echo NMR spectra of ^{155}Gd , ^{157}Gd , and ^1H at 1.3 K for (a) $\text{Gd}_2\text{Fe}_{17}$, (b) $\text{Gd}_2\text{Fe}_{17}\text{H}_{2.3}$, (c) $\text{Gd}_2\text{Fe}_{17}\text{H}_{5.8}$, and at 77 K for (d) $\text{Gd}_2\text{Fe}_{17}\text{H}_{2.3}$.

1.3 and 77 K. All the peaks in Fig. 5(a) are certainly from the ^{155}Gd and ^{157}Gd isotopes, and will not be discussed here.¹⁵ It can be seen that hydrogenation makes the ^{155}Gd and ^{157}Gd spectra complicated because of changes in the quadrupolar interactions as well as the hyperfine fields. However, the strong, broad peak occurring near 70 MHz at 1.3 K can clearly be attributed to ^1H . At 77 K, this peak shifts to 68.8 MHz and becomes sharper [Fig. 5(d)]. When an external magnetic field of 6.0 kOe was applied, the peak shifted to 85.0 MHz and became broader. This result indicates the hyperfine field of ^1H is in the same direction as the net magnetization.

Structural and magnetic studies of $\text{Er}_2\text{Fe}_{17-x}\text{M}_x\text{C}_y$ ($\text{M}=\text{Ga}$ and Al) compounds

W. C. Chang, S. L. Lu, S. K. Chen,^{a)} and Y. D. Yao

Department of Physics, National Chung Cheng University, Ming-Hsiung, Chia-Yi, Taiwan, Republic of China

The effect of Ga and Al substitution for Fe on the structural and magnetic properties of the $\text{Er}_2\text{Fe}_{17-x}\text{M}_x\text{C}_y$ ($\text{M}=\text{Ga}, \text{Al}; x=0-4, y=0-2$) compounds was investigated. It was found that Ga is superior to Al in stabilizing the single-phase $\text{Er}_2\text{Fe}_{17-x}\text{M}_x\text{C}_y$ compounds. The hexagonal $\text{Th}_2\text{Ni}_{17}$ -type structure persisted in almost all alloys with the exception of $\text{Er}_2\text{Fe}_{13}\text{Ga}_4\text{C}$ and $\text{Er}_2\text{Fe}_{13}\text{Ga}_4\text{C}_2$. These two compounds exhibited a rhombohedral $\text{Th}_2\text{Zn}_{17}$ structure. Both the Curie temperature and magnetization can be enhanced with a certain amount of Ga or Al substitution. But they decreased almost monotonically with the increase of Ga or Al content in $\text{Er}_2\text{Fe}_{17-x}\text{M}_x\text{C}_y$ ($x>1, y>0$). The spin reorientation temperature, T_{sr} , was influenced by both carbon interstitial and Ga or Al substitution for Fe and ascribed to the increase of the c -axis uniaxial anisotropy of the Er^{3+} sublattice by the modification of electron structure around it. The highest T_{sr} of 241 K appears in the compound $\text{Er}_2\text{Fe}_{14}\text{Ga}_3\text{C}$. © 1996 American Institute of Physics. [S0021-8979(96)32508-0]

I. INTRODUCTION

$\text{R}_2\text{Fe}_{17}\text{C}_x$ compounds have been extensively studied because their thermal stability is superior to that of nitrogenated compounds. The addition of Ga and Al was reported to further stabilize the $\text{R}_2\text{Fe}_{17}\text{C}_x$ compounds with high carbon concentration.^{1,2} The solubility of Ga and Al in $\text{R}_2\text{Fe}_{17}\text{C}_x$ changes with R elements and consequently determines the magnetic anisotropy of the carbides. Few papers have ever reported their effects in a $\text{R}=\text{Er}$ system^{3,4} and the range of the alloy compounds has not been widely covered. In this study, we first investigate the single-phase region of the $\text{Er}_2\text{Fe}_{17-x}\text{M}_x\text{C}_y$ ($\text{M}=\text{Ga}$ and $\text{Al}; x=0-4, y=0-2$) compounds, and then the effects of Ga and Al replacement in $\text{R}_2\text{Fe}_{17}\text{C}_x$ compounds on the Curie temperature (T_C), magnetization (M_s), and spin reorientation temperature (T_{sr}). A comparison and discussion of the Ga and Al effect in these $\text{Er}_2\text{Fe}_{17-x}\text{M}_x\text{C}_y$ systems will be presented.

II. EXPERIMENT

The studied samples, 2 g for each, with the nominal composition $\text{Er}_2\text{Fe}_{17-x}\text{M}_x\text{C}_y$ ($\text{M}=\text{Ga}$ and $\text{Al}; x=0-4, y=0-2$) were prepared by arc melting in a high purity argon atmosphere. The alloys were remelted at least three times to ensure homogeneity and then followed with a homogenization treatment at 1100 °C for 24 h. X-ray diffraction with $\text{Cu } K\alpha$ radiation was adopted to determine the single-phase and crystallographic structure. The room temperature magnetization of the samples was measured with a vibrating sample magnetometer (VSM). The Curie temperatures were determined from the change of weight with temperature measured by thermal gravimetric analysis (TGA). Finally, the spin reorientation temperatures were determined from the magnetization versus temperature curves measured by a superconducting quantum interference device magnetometer in a magnetic field of 100 Oe.

III. RESULTS AND DISCUSSION

From x-ray diffraction studies, it was found that Ga is superior to Al in stabilizing the formation of single-phase $\text{Er}_2\text{Fe}_{17-x}\text{M}_x\text{C}_y$ alloys when $\text{M}=\text{Ga}$ or Al . For the alloy with $\text{M}=\text{Ga}$, a single-phase region persisted in the alloy with $x=4, y=2$ it mainly exhibited the hexagonal $\text{Th}_2\text{Ni}_{17}$ -type structure with the exception of the alloy with $x=4, y=1-2$ showing the rhombohedral $\text{Th}_2\text{Zn}_{17}$ structure. However, for alloys with $\text{M}=\text{Al}$, a single phase could only persist in the alloy with a $x=4, y=1$ hexagonal $\text{Th}_2\text{Ni}_{17}$ -type structure which appeared in all of the alloys. Table I shows the lattice parameters $a, c, V, \Delta V/V$, and types of structure of the $\text{Er}_2\text{Fe}_{17-x}\text{M}_x\text{C}_y$ ($\text{M}=\text{Ga}$ and Al) compounds with single phase. The different ability in stabilizing the $\text{Th}_2\text{Ni}_{17}$ -type carbide structure between $\text{M}=\text{Ga}$ and Al may be due to the fact that the electronegativity difference of $\text{Al}-\text{C}$ (0.94) is

TABLE I. The lattice parameters, $a, c, V, \Delta V/V$, and types of structure of the $\text{Er}_2\text{Fe}_{17-x}\text{M}_x\text{C}_y$ compounds ($\text{M}=\text{Ga}, \text{Al}; x=0-4, y=0-2$).

FIG. 1. The Curie temperatures of the $Er_2Fe_{17-x}M_xC_y$ compounds (a) $M=Ga$ and (b) $M=Al$.

higher than that of $Ga-C$ (0.74);⁵ too much carbon in $Er_2Fe_{17-x}Al_xC_y$ more easily leads to the decomposition of the compound to α -Fe, AlC , and ErC than is the case in $Er_2Fe_{17-x}Ga_xC_y$. On the other hand, the lattice parameters a , c , V , and $\Delta V/V$ all increase with an increase of x and y in both the $M=Ga$ and Al compounds. In comparison with the value of Er_2Fe_{17} , the volume expansion ratio of the unit cell, $\Delta V/V$, for the compound with $M=Ga$ and Al is the same, 6.3%, at the condition of $x=4$, $y=1$. It reaches the highest value, 7.1%, in the $Er_2Fe_{13}Ga_4C_2$ compound.

The Curie temperatures of the $Er_2Fe_{17-x}M_xC_y$ ($M=Ga$ and Al) compounds are shown in Figs. 1(a) and 1(b). It can be seen that T_C increases with increasing carbon content (y) of the compound. For $Er_2Fe_{17-x}Ga_x$, T_C increases monotonically with x , reflecting the fact that the substitution of Ga for Fe enhances the $Fe-Fe$ exchange interaction caused by the expansion of the lattice constant. For $Er_2Fe_{17-x}Ga_xC$, T_C initially increases with x , then decreases. A maximum T_C of 560 K appears at $x=1$. This implies that the $Fe-Fe$ exchange interaction may decrease due to the lattice overexpansion caused by the effect of Ga substitution and C interstitial substitution at the same time. A similar situation is also found for the compound $Er_2Fe_{17-x}Ga_xC_2$ so that T_C again decreases slightly with x . For $M=Al$, the trend of T_C variation with x in the alloys without carbon and with carbon ($y=1$) is almost the same as for the alloys with $M=Ga$. However, the value of T_C is lower in the Al substituted compound. A T_C of only 538 K was obtained in the $Er_2Fe_{16}AlC$ compound, which is lower than that of the $Er_2Fe_{16}GaC$ compound (560 K).

Figures 2(a) and 2(b) plot the room temperature saturation magnetization, M_s , of the single-phase $Er_2Fe_{17-x}M_xC_y$ compounds with $M=Ga$ and $M=Al$, respectively. For the alloys without carbon, M_s reaches a peak value at $x=2$ for $M=Ga$ (74.2 emu/g) and at $x=1$ for $M=Al$ (75.6 emu/g). The occurrence of the M_s peak may be determined by the

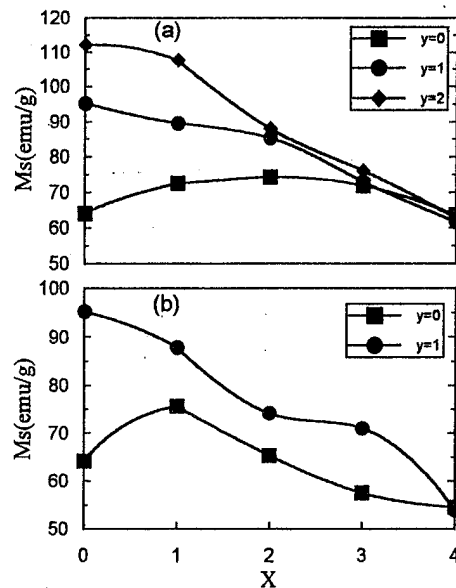

FIG. 2. The room temperature saturation magnetization of the $Er_2Fe_{17-x}M_xC_y$ compounds (a) $M=Ga$ and (b) $M=Al$.

counterbalance between the increase of the $Fe-Fe$ sublattice exchange interaction due to Ga or Al substitution for Fe and the decrease of the total Fe moment due to the dilution effect by the nonmagnetic elements, i.e., Ga or Al , substitution. However, for the alloys with carbon, M_s decreases almost monotonically with an increase of x in both Ga and Al substituted alloys. The slope of decrease is a little larger for the alloys with $M=Al$ than for that of $M=Ga$.

Figure 3 shows the temperature dependence of the magnetization of the $Er_2Fe_{17-x}Ga_xC$ compounds measured by a superconducting quantum interference device magnetometer in a magnetic field of 100 Oe. It can clearly be found that each curve has a maximum magnetization at certain temperature, called the spin reorientation temperature (T_{sr}), while the spin reorientation temperature of those compounds change with the amount of Ga substitution, x . The same phenomenon is also found in the Al substituted compounds. Figures 4(a) and 4(b) exhibit the summarized composition dependence of the T_{sr} of the $Er_2Fe_{17-x}Ga_xC_y$

FIG. 3. Temperature dependence of the room temperature magnetization of the $Er_2Fe_{17-x}Ga_xC$ compounds measured in a magnetic field of 100 Oe.

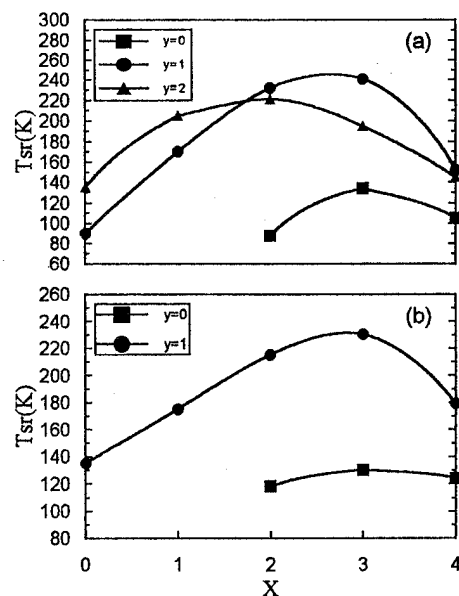

FIG. 4. The spin reorientation temperatures of the $\text{Er}_2\text{Fe}_{17-x}\text{M}_x\text{C}_y$ compounds (a) $\text{M}=\text{Ga}$ and (b) $\text{M}=\text{Al}$.

and $\text{Er}_2\text{Fe}_{17-x}\text{Al}_x\text{C}_y$ compounds, respectively. Basically, the trend of T_{sr} variation is the same in the above two compounds with $y=0$ and $y=1$. It first increases with x , then decreases again, and their peak values all appear at the alloy with $x=3$. Despite the variation of T_{sr} in $\text{Er}_2\text{Fe}_{17-x}\text{Ga}_x\text{C}_2$ compounds being the same as in previous alloys, its peak value is lower and appears at the alloy with $x=2$.

The T_{sr} of the alloys studied is normally determined by the competition between the temperature dependence of the c -axis anisotropy field of the Er^{3+} sublattice [$K_1(\text{Er}^{3+})$] and the planar anisotropy of the Fe sublattice [$K_1(\text{Fe})$]. Any parameter altering the above two factors will somehow change T_{sr} . The rare earth sublattice anisotropy in the crystal field term can be expressed as follows:

$$K_1(R) = -\frac{3}{2}\alpha_J \langle r_{4f}^2 \rangle \langle 3J_z^2 - J(J+1) \rangle \bar{A}_2,$$

where α_J is the second-order Stevens factor, the quantities in brackets are expectation values, and \bar{A}_2 is the second-order crystal field parameter, which is strongly influenced by the rare earth electron charge asphericity.⁶ It has been shown that the first-order magnetic anisotropy constant, K_1 , of Er^{3+} , is

positive,⁷ and it is governed by its electron structure around the sublattice, or the value of \bar{A}_2 . After adding the carbon to the alloy, the electron structure of the Er^{3+} sublattice was modified by the carbon interstitial, and therefore the value of \bar{A}_2 becomes more negative, leading to the enhancement of its $K_1(\text{Er}^{3+})$ value. In addition, it has been reported that the carbon interstitial also may reduce the degree of planar anisotropy of the Fe sublattice,⁸ i.e., $K_1(\text{Fe})$ changes to less negative, as a result, both effects lead to the increment of K_1 (total) [$=K_1(\text{Er}^{3+})+K_1(\text{Fe})$] and the spin reorientation temperature—the temperature at which the anisotropy changes from basal to axial as the temperature decreases—in $\text{Er}_2\text{Fe}_{17}\text{C}_y$ alloys. The increase of T_{sr} with an increasing carbon interstitial up to $y=1$ is therefore ascribed to the above two effects. On the other hand, according to a previous study,⁹ the crystal field of the Er^{3+} can also be altered by means of Ga or Al substitution for Fe through the hybridization of the $5d$ and $6f$ valence electrons of Er^{3+} and the valence electrons of the neighboring atoms, such as Ga or Al, which also may result in the variation of magnitude of the Er valence electron asphericity and the value of \bar{A}_2 . This might explain the increases of T_{sr} with the increase of x up to $x=3$. In the mean time, the value of T_{sr} in the Ga containing alloys is found to be higher than that of Al containing alloys, implying that Ga has a stronger effect in enhancing $K_1(\text{Er}^{3+})$ than does Al.

Thermal stability of nanostructured $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ compounds prepared by ball milling

O. Mao, Z. Altounian, J. Yang, and J. O. Ström-Olsen

Centre for the Physics of Materials, Department of Physics, McGill University, Montréal, Québec H3A 2T8, Canada

The thermal stability of ball-milled nanocrystalline $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ interstitial compounds has been investigated. $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ decomposes into a mixture of phases upon annealing above a certain decomposition temperature, T_{d1} , which depends on the carbon concentration in the compound. Annealing above a certain temperature $T_{d2}(>T_{d1})$, the $\text{Sm}_2\text{Fe}_{14}\text{C}$ phase starts to form. The amount of the $\text{Sm}_2\text{Fe}_{14}\text{C}$ phase increases with increasing annealing temperature at the expense of the $\text{Sm}_2\text{Fe}_{17}$ carbide until T_{r1} , at which temperature $\text{Sm}_2\text{Fe}_{14}\text{C}$ starts to recombine with other phases to form the $\text{Sm}_2\text{Fe}_{17}$ carbide. For the starting composition with $x < 1.5$, the $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ single phase can be recovered above the recovery temperature $T_{r2}(>T_{r1})$. © 1996 American Institute of Physics. [S0021-8979(96)32608-7]

I. INTRODUCTION

The presence of interstitial nitrogen and/or carbon atoms in a $\text{Sm}_2\text{Fe}_{17}$ intermetallic compound of the $\text{Th}_2\text{Zn}_{17}$ structure type results in useful hard magnetic properties.^{1,2} However, the interstitial compound is metastable, and decomposes into a mixture of phases upon annealing. Thermal stability is, therefore, an important consideration in the processing and practical use of these materials. $\text{Sm}_2\text{Fe}_{17}$ carbides prepared by a gas-solid reaction (GSR) with hydrocarbon gases are unstable upon heating.³ The decomposition schemes are rather complicated in the case of quaternary systems containing Sm, Fe, C, and H. Meanwhile, it is reported⁴ that the $\text{R}_2\text{Fe}_{14}\text{C}$ structure of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ type is more stable than $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ at temperatures lower than a transition temperature T_i ($T_i \sim 980^\circ\text{C}$ for $\text{R}=\text{Sm}$). Solid state transformation of $\text{Sm}_2\text{Fe}_{14}\text{C}$ into $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ compound occurs when the annealing temperature is held above T_i and the $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ structure persists even when subjected to subsequent annealing below T_i .⁴ In this contribution we report the thermal stability of nanostructured $\text{Sm}_2\text{Fe}_{17}$ carbides prepared by ball milling (BM).

II. EXPERIMENTAL TECHNIQUES

$\text{Sm}_2\text{Fe}_{17}\text{C}_x$ samples used for this study were synthesized by solid-solid reaction (SSR) of $\text{Sm}_2\text{Fe}_{17}$ /graphite blends. The blends are mixtures of two pure phases, $\text{Sm}_2\text{Fe}_{17}$ and graphite, prepared by room temperature BM. SSR was carried out at 450°C for 10 h. The details of the process are given in Ref. 5. All sample handling procedures were performed in a specially designed glove box with oxygen and humidity levels of less than 1 ppm. For heat treatments, the samples were sealed in a quartz tube under Ar. The annealing time varied with the annealing temperature. Above 700°C an annealing time of 30 min was adopted, while for lower temperatures, the annealing time was 1 h or longer (up to 10 h for temperatures less than 600°C). For structural analysis, x-ray diffraction (XRD) was performed in an automated Nicolet-Stoe powder diffractometer with graphite monochromated $\text{Cu } K_\alpha$ radiation. Curie temperatures, T_C 's, were measured by thermomagnetometry using a Perkin-Elmer

thermogravimetric analyzer (TGA-7) in a small magnetic field gradient (TGAM). Differential scanning calorimetry (DSC) was performed using a Perkin-Elmer DSC-2C calorimeter.

III. RESULTS AND DISCUSSION

A. Thermal stability of $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ compounds

The powders prepared by SSR were almost single-phase $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ with a small amount of $\alpha\text{-Fe}$. Upon heating at 800°C for 30 min, the samples decomposed into mixtures of phases, as shown in Fig. 1. Besides $\alpha\text{-Fe}$ two other magnetic phases were detected by TGAM. The phase with the lower T_C ($\sim 190^\circ\text{C}$) is $\text{Sm}_2\text{Fe}_{17}\text{C}_y$ (y may differ from x) and the phase with $T_C \sim 310^\circ\text{C}$ is identified as $\text{Sm}_2\text{Fe}_{14}\text{C}^6$ (compare XRD patterns 3 and 8 in Fig. 1). The $\text{Sm}_2\text{Fe}_{17}\text{C}_y$ phase coexists with $\text{Sm}_2\text{Fe}_{14}\text{C}$ for $x < 1.0$ and vanishes for $x > 1$. Due

FIG. 4. DSC thermograms for (1) $\text{Sm}_2\text{Fe}_{17}\text{C}_{0.5}$ ball-milled blends; (2) $\text{Sm}_2\text{Fe}_{17}\text{C}_{2.0}$ ball-milled blends.

to the complicated structure of both $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ and $\text{Sm}_2\text{Fe}_{14}\text{C}$, TGAM gives a clearer indication of the presence of these phases as shown in Fig. 2. To understand the nature of the decomposition, $\text{Sm}_2\text{Fe}_{17}\text{C}_{0.5}$ and $\text{Sm}_2\text{Fe}_{17}\text{C}_{1.0}$ single-phase compounds have been prepared for comparison by direct alloying (DA). The 2:17 single-phase structure is formed upon annealing the as-made ingots at 1150 °C for 5 h and persists even under subsequent annealing treatment. This result is in agreement with that reported by Mooij and Buschow.⁴ However when the DA ingot was ball milled at the same milling condition as that for preparing the SSR sample, the resulting powder was unstable when annealed at 800 °C. The results of TGAM performed on both DA and SSR samples are given in Fig. 3. Scans 2 and 3 are essentially identical, suggesting that the decomposition is induced by BM. The DA $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ ingot homogenized at 1150 °C for 5 h has grain sizes around 50 μm observed by an optical metallographic microscope. The grain sizes are estimated to be 60 nm in the ball-milled powder from the widths of the Bragg peaks (subtracting out the broadening due to the intrinsic instrumental resolution of the diffractometer and the strain in the lattice). The above results suggest that BM enhances the atomic diffusion as the reduction of grain size leads to an increase in grain boundaries destabilizing the

FIG. 3. Thermomagnetic scans of samples annealed at 800 °C: (1) $\text{Sm}_2\text{Fe}_{17}\text{C}_{0.5}$ ingot of direct alloying, DA (1150 °C annealed for 5 h); (2) $\text{Sm}_2\text{Fe}_{17}\text{C}_{0.5}$ ingot of DA after ball milling for 3 h; and (3) $\text{Sm}_2\text{Fe}_{17}\text{C}_{0.5}$ prepared by the SSR technique.

$\text{Sm}_2\text{Fe}_{17}\text{C}_x$ compounds. The enhanced carbon diffusion results in a faster carbiding process in the powders. This is clearly shown in the DSC thermograms (Fig. 4) of the blends where an exothermal reaction occurs at a relatively low temperature region between 300 and 500 °C, indicating the formation of $\text{Sm}_2\text{Fe}_{17}$ carbides. Integration over this peak area gives the enthalpy of formation of the carbide as ~ 20 kJ/mol-C atoms. The second exothermal peak on curve 2, at high temperatures, corresponds to the decomposition of the $\text{Sm}_2\text{Fe}_{17}$ carbide, while the heat evolution associated with the decomposition is insignificant for $x < 1.5$ as show in scan 1 in Fig. 4.

B. Decomposition schemes

TGAM results in Fig. 5 show the evolution of $\text{Sm}_2\text{Fe}_{17}\text{C}_{1.0}$ with annealing temperature. Annealing between 600 and 700 °C results in the precipitation of $\alpha\text{-Fe}$ and annealing above 740 °C results in the formation of the $\text{Sm}_2\text{Fe}_{14}\text{C}$ phase. Above 1100 °C, the $\text{Sm}_2\text{Fe}_{17}\text{C}_{1.0}$ single phase is recovered. Similar sequential annealings have been

FIG. 5. Thermomagnetic scans of SSR $\text{Sm}_2\text{Fe}_{17}\text{C}_{1.0}$ powders annealed at various temperatures: (1) 480 °C; (2) 700 °C; (3) 740 °C; (4) 800 °C; (5) 1000 °C, and (6) 1100 °C.

TABLE I. Characteristic temperatures ($^{\circ}\text{C}$) for the various $\text{Sm}_2\text{Fe}_{17}$ carbides.

Compounds	T_{d1}	T_{d2}	T_{r1}	T_{r2}
$\text{Sm}_2\text{Fe}_{17}\text{C}_{0.5}$	528	...	800	1000
$\text{Sm}_2\text{Fe}_{17}\text{C}_{1.0}$	569	740	1000	1100
$\text{Sm}_2\text{Fe}_{17}\text{C}_{1.5}$	544	...	1100	...
$\text{Sm}_2\text{Fe}_{17}\text{C}_{3.0}$	512
$\text{Sm}_2\text{Fe}_{17}\text{C}_{6.0}$	512

performed for $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ with various x . The evolution of $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ during annealing comprises several stages. (i) At a certain temperature, T_{d1} , $\alpha\text{-Fe}$ begins to precipitate and $\text{Sm}(\text{Fe})$ carbide may also form to maintain the balance of the reaction equation

TGAM scans were used to determine T_{d1} , which is defined as the onset of the increase in magnetization. (ii) At a higher temperature, T_{d2} , the $\text{Sm}_2\text{Fe}_{14}\text{C}$ phase begins to form and its amount increases with the annealing temperature at the expense of $\text{Sm}_2\text{Fe}_{17}\text{C}_y$. For starting compositions with $x > 1$, the 2:17 phase disappears completely at a certain temperature. (iii) At still higher temperatures, $T_{r1} > T_{d2}$, the $\text{Sm}_2\text{Fe}_{14}\text{C}$ phase starts to recombine with other phases forming the $\text{Sm}_2\text{Fe}_{17}\text{C}_z$ structure. (iv) At a temperature above $T_{r2} (> T_{r1})$, the recovery temperature, the $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ single phase is recovered (only for $x < 1.5$). The various reaction temperatures are listed in Table I. For $x > 1.5$, the single-phase 2:17 structure cannot be recovered.

IV. CONCLUSIONS

The ball-milled nanocrystalline single-phase $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ compounds are formed, upon heat treatment, with a formation enthalpy of ~ 20 kJ/mol C. This phase decomposes into a mixture of phases upon annealing above a certain decomposition temperature, T_{d1} , which depends on x , while the $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ ingots prepared by direct alloying are stable after annealing at 1150°C . Destabilizing of the direct alloyed $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ compound upon BM may result from the fast atomic diffusion enhanced by the reduction of grain sizes. Annealing above a certain temperature $T_{d2} (> T_{d1})$, the $\text{Sm}_2\text{Fe}_{14}\text{C}$ phase starts to form at the expense of the $\text{Sm}_2\text{Fe}_{17}$ carbide until T_{r1} , where $\text{Sm}_2\text{Fe}_{14}\text{C}$ starts to react with other phases to form the $\text{Sm}_2\text{Fe}_{17}$ carbide. For starting compositions with $x < 1.5$, the $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ single phase is recovered above the recovery temperature $T_{r2} (> T_{r1})$.

Synthesis, structural, and magnetic properties of $R_3(\text{Fe,Cr})_{29}$ intermetallic compounds ($R=\text{Ce,Nd}$) and their nitrides are reported. The $\text{Ce}_3(\text{Fe,Cr})_{29}$ sample was single phase while the $R=\text{Nd}$ ingot contained significant contamination by secondary phases. X-ray analysis reveals the monoclinic $\text{Nd}_3(\text{Fe,Ti})_{29}$ -type structure with space group $A2/m$. The unit cell dimensions for the parent $R=\text{Ce}$ compound are $a=10.513(2)$ Å, $b=8.478(1)$ Å, $c=9.657(1)$ Å, $\beta=96.75(1)^\circ$, and $V=854.70$ Å³. In the case of Ce a relative unit cell expansion of 6.5% is observed upon nitrogenation. The Curie temperature is 326 K for Ce and 432 K for Nd and becomes 612 and 633 K for Ce-nitride and Nd-nitride, respectively. The room temperature magnetization at 5 T is 58.2 A m²/kg for Ce and 104.1 A m²/kg for Nd and increases after nitrogenation to 109.8 and 127.2 A m²/kg for Ce and Nd, respectively. The average hyperfine field of the $R=\text{Ce}$ compound at 85 K is 19.2 T. X-ray diffraction measurements on a magnetically aligned powder of $\text{Ce}_3(\text{Fe,Cr})_{29}$ indicate that the magnetocrystalline anisotropy of the iron sublattice is most likely an in-plane type. Mössbauer spectrum analysis provided evidence that the Cr enters the dumbbell sites. © 1996 American Institute of Physics. [S0021-8979(96)32708-3]

The synthesis of the novel ternary compound $R_3(\text{Fe,T})_{29}$, has been reported for $R=\text{Y, Ce, Pr, Nd, Sm, Gd, and Tb}$; and $T=\text{Ti, Cr, V, Mn, and Mo}$.¹⁻¹³ The structure is more accurately described in the $A2/m$ space group¹¹ than in the $P2_1/c$.¹² The arrangement of R, Fe, and T atoms is a combination of the arrangements observed in the well-known rhombohedral $\text{Th}_2\text{Zn}_{17}$ and tetragonal ThMn_{12} structures, thus affecting the magnetic properties of these compounds in a predictable manner. The Curie temperature T_C values are intermediate between the T_C values of the 1:12 and 2:17 compounds.⁴ Point charge calculations¹⁴ have shown that the values of the $A_{20}(\text{R})$ crystal field coefficients for the $4i$ site (2:17 like) and $2a$ site (1:12 like) are of opposite sign, as is also the case for the R sites in the 2:17 and 1:12 structures, and this is probably the reason for the difficulty encountered when describing the magnetic anisotropy for 3:29 compounds with magnetic R ions. For this reason it is important to synthesize and study 3:29 compounds with nonmagnetic R, such as Y or Ce, where only the iron sublattice contributes to the magnetocrystalline anisotropy. The synthesis and the magnetic properties of $\text{Ce}_3\text{Fe}_{27.5}\text{Ti}_{1.5}$ and its nitride have been reported in a previous study.⁵ Analysis of ⁵⁷Fe Mössbauer spectra on magnetically aligned samples of $\text{Ce}_3\text{Fe}_{27.5}\text{Ti}_{1.5}$ has given evidence for an in-plane magnetocrystalline anisotropy of the iron sublattice.⁵ X-ray powder diffraction on magnetically aligned powder of $\text{Y}_3(\text{Fe,Ti})_{29}$ has led to similar conclusions.¹⁵ Preliminary results on $\text{Ce}_3\text{Fe}_{24.9}\text{Cr}_{4.1}$ are reported in Ref. 3, but that sample was not single phase since an excess in Ce was added in the starting composition. Here, we report the synthesis, and the structural and magnetic properties of higher quality single-phase compounds with stoichiometric starting compositions of $\text{Nd}_3\text{Fe}_{24.5}\text{Cr}_{4.5}$ and $\text{Ce}_3\text{Fe}_{25}\text{Cr}_4$. The existence of single-phase

$\text{Ce}_3\text{Fe}_{25}\text{Cr}_4$ and a phase with a composition of $\text{Nd}_3\text{Fe}_{24.5}\text{Cr}_{4.5}$ extends the solubility limit of the T atoms in the Fe sites of the 3:29 compounds.

The $R_3(\text{Fe,Cr})_{29}$ ingots with the nominal starting composition of $\text{Ce}_{9.4}\text{Fe}_{78.1}\text{Cr}_{12.5}$ and $\text{Nd}_{9.4}\text{Fe}_{76.6}\text{Cr}_{14}$ were prepared by induction melting high purity elemental constituents. The ingots were wrapped in tantalum foil, heat treated in vacuum at various temperatures for three days, and water quenched. Fine powder of the annealed alloys (<37 μm) was nitrified in high purity nitrogen gas at 673 K and at 4 atm for 24 h. All samples were characterized by means of x-ray powder diffraction (XRD) using $\text{Cu } K_\alpha$ radiation, Rietveld analysis, thermomagnetic analysis (TMA), and electron beam microprobe analysis (energy dispersive x-ray analysis). XRD on magnetically aligned powder samples was carried out to study the magnetocrystalline anisotropy of the compounds. Magnetization measurements on powder samples were performed by a superconducting quantum interference device magnetometer with a maximum field of 5 T at 5 and 300 K. The ⁵⁷Fe Mössbauer spectra were collected at 85 K on a conventional acceleration spectrometer with a ⁵⁷Co(Rh) source. The ac-magnetic susceptibility measurements were done in the temperature range of 77–300 K using a home-made ac susceptometer.

The as-cast $\text{Nd}_3(\text{Fe,Cr})_{29}$ ingot was split into smaller pieces which were annealed at 1325, 1275, 1225, and 1200 K for three days. At 1325 K the result was a mixture of the 1:12 and 2:17 phases. In the samples annealed at 1275, 1225, and 1200 K, the main phase was $\text{Nd}_3(\text{Fe,Cr})_{29}$ but contaminant phases including $\text{Nd}(\text{Fe,Cr})_7$ and Fe_3Cr were also detected. For the $R=\text{Ce}$ materials single-phase $\text{Ce}_3(\text{Fe,Cr})_{29}$ was achieved after annealing at 1175 K for three days. Electron microprobe analysis yielded an average chemical formula $\text{Ce}_{2.97}\text{Fe}_{24.93}\text{Cr}_{4.1}$. In the case of Nd the primary phase had a composition $\text{Nd}_3\text{Fe}_{24.5}\text{Cr}_{4.5}$ and the secondary 1:7 phase

TABLE I. Lattice parameters for $\text{Ce}_3(\text{Fe,Cr})_{29}$, $\text{Ce}_3(\text{Fe,Cr})_{29}\text{N}_4$, and $\text{Nd}_3(\text{Fe,Cr})_{29}$ determined from powder x-ray diffraction ($\text{Cu K}\alpha$) using Rietveld analysis.

Sample	a (Å)	b (Å)	c (Å)	β (°)	V (Å ³)
$\text{Ce}_3(\text{Fe,Cr})_{29}$	10.513(2)	8.487(1)	9.657(1)	96.75(1)	854.70
$\text{Ce}_3(\text{Fe,Cr})_{29}\text{N}_4$	10.749(6)	8.664(5)	9.848(7)	96.89(2)	910.59
$\text{Nd}_3(\text{Fe,Cr})_{29}$	10.603(3)	8.546(3)	9.699(3)	96.80(2)	872.62

$\text{NdFe}_{6.16}\text{Cr}_{0.84}$, respectively. Rietveld analysis yielded a phase composition of 71.2% 3:29, 22.3% 1:7, and 6.5% Fe_3Cr . Thus, an overall composition of $\text{Nd}_{9.5}\text{Fe}_{76.7}\text{Cr}_{13.8}$ was calculated very close to the nominal composition of the starting material.

After nitrogeneration at 673 K for 12 h both $\text{R}=\text{Ce}$ and $\text{R}=\text{Nd}$ showed a mixture of nitrated and non-nitrated phases. After cumulative treatment under the same conditions the non-nitrated compound practically disappeared. The nitrated $\text{R}=\text{Ce}$ compound showed a lattice expansion of 6.5%. Crystallographic and magnetic data of the parent and the nitrated Ce and Nd compounds are given in Tables I and II. The lattice parameters a , b , c , and β were deduced applying the Rietveld refinement method and using the $A2/m$ space group.

Curie temperature (T_C) values were determined by TMA with a heating rate of 5°/min. The Curie temperatures for $\text{Ce}_3\text{Fe}_{25}\text{Cr}_4$ are very close to the values reported for $\text{Ce}_3\text{Fe}_{27.5}\text{Ti}_{1.5}$.^{3,4} In contrast, the magnetization values are lower for the $\text{T}=\text{Cr}$ group, reflecting the magnetic dilution of the iron sublattice by the large amount of Cr and suggesting that the Cr ion is essentially nonmagnetic. In the ac-susceptibility versus temperature curve of $\text{Nd}_3(\text{Fe,Cr})_{29}$ a magnetic transition at about 160 K was observed (Fig. 1). From the shape of the magnetization versus temperature curve it was concluded that this transition most likely corresponds to an ordering temperature of an impurity rather than to spin reorientation.

The XRD patterns of a magnetically aligned powder sample $\text{Ce}_3(\text{Fe,Cr})_{29}$ with the magnetic field normal to the sample holder, are shown in Fig. 2. The increase in the intensity of the (4 0 -2) reflection is the most significant change. The intensity of the (2 0 4) reflection decreases slightly. There is not an obvious change in the intensity of the (0 4 0) reflection. The [4 0 -2] crystallographic direction is related to the c axis of the 1:12 structure. On the other hand, the [4 0 -2] and the [0 4 0] directions lie on the a - b plane of the 2:17 structure.¹¹ The magnetocrystalline anisotropy of Ce-Fe intermetallics is dominated by the iron sublattice which is uniaxial in the case of the 1:12 compounds

(along the c axis) and in the basal plane in the case of 2:17. Our results are similar to those observed by Li *et al.*¹⁵ concerning the $\text{Y}_3(\text{Fe,Ti})_{29}$ compound. The only difference is that, besides the changes of the (4 0 -2) and (2 0 4) reflections, they have observed a slight increase of the [0 4 0] reflection. From the changes in the intensities of the above-mentioned reflections they have assumed that in 3:29 the iron sublattice should present in-plane anisotropy where the easy plane is determined by the [4 0 -2] and the [0 4 0] directions, the [4 0 -2] direction being dominant. In the case of Cr the fact that there is no significant change in the intensity of the (0 4 0) reflection may be due to a stronger influence of 1:12 leading to an in-plane anisotropy with so strong a preferred direction, [4 0 -2], that no change in the (0 4 0) line can be observed. The presence of uniaxial anisotropy along the [4 0 -2] direction cannot be excluded but in this case the (0 4 0) reflection should decrease. Nevertheless, as concluded from other studies as well^{8,11,16} the above-mentioned crystallographic directions play an important role for the anisotropy of the 3:29 system.

In Fig. 3 the ^{57}Fe Mössbauer spectra of the parent $\text{R}=\text{Ce}$ compound at 85 K is shown. The spectral analysis employed five magnetically split sextets with variable linewidths. In a recent work we analyzed the Mössbauer spectra of the $\text{Pr}_3\text{Fe}_{27.5}\text{Ti}_{1.5}$ compound by using four magnetically split sextets.¹⁷ In that analysis the 11 crystallographic iron sites were divided into four groups according to the number of nearest neighbors (nn) and the average bond lengths taking into account the results of a recent neutron diffraction study

FIG. 1. The ac-susceptibility vs temperature for the annealed $\text{Nd}_3(\text{Fe,Cr})_{29}$ ingot.

TABLE II. Saturation magnetization (M_s) and Curie temperatures (T_C) for two $\text{R}_3(\text{Fe,Cr})_{29}$ phases, $\text{R}=\text{Ce}$ and Nd , and their respective nitrides, M_s is provided as magnetization per mass ($\text{A m}^2/\text{kg}$) and per volume (kG).

Sample	M_s ($\text{A m}^2/\text{kg}$)/(kG) $T=5$ K	M_s ($\text{A m}^2/\text{kg}$)/(kG) $T=300$ K	T_C (K)
$\text{Ce}_3(\text{Fe,Cr})_{29}$	104.4/10.36	58.2/5.78	316
$\text{Ce}_3(\text{Fe,Cr})_{29}\text{N}_4$	126.4/11.86	109.8/10.30	612
$\text{Nd}_3(\text{Fe,Cr})_{29}$	128.2/12.47	101.7/9.89	432
$\text{Nd}_3(\text{Fe,Cr})_{29}\text{N}_4$	137.3/11.69	127.2/12.62	633

FIG. 2. X-ray diffraction ($\text{Cu } K_\alpha$) data for $\text{Ce}_3(\text{Fe,Cr})_{29}$ is presented for (a) a randomly oriented powder, and (b) magnetically aligned powder. The magnetic alignment was performed at room temperature using a field perpendicular to the sample plane.

on $\text{Nd}_3(\text{Fe,Ti})_{29}$ that Fe2, Fe3, and Fe6 are partially occupied by Ti, 30%, 20%, and 10%, respectively.¹⁸ That approach has led to an area ratio of $A:B:C:D=1:2:1.5:1.2$ where site A corresponds to the dumbbell sites. The subspectrum with the largest hyperfine field has been assigned to the Fe2, Fe3, and Fe6 (dumbbell sites group) based on the fact that these iron sites present the largest number of nearest neighbors and the largest values of the average bond lengths compared to the other sites. In the case of $\text{Ce}_3\text{Fe}_{25}\text{Cr}_4$ it was assumed that the 4 Cr-substituting atoms are equally distributed on the three dumbbell sites Fe2, Fe3, and Fe6. These iron sites coincide with the 8i site of the related ThMn_{12} structure in the transformation $3:29 \rightarrow 1:12$ which is preferentially occupied by Ti. Introducing 4 Cr atoms, instead of 1.5 Ti atoms, in the dumbbell sites decreases the number of nn of the rest of the sites rather than of the dumbbell itself and of course the area ratio. Thus, the fit was made with five components according to the number of nn, with variable linewidths and with an area ratio $A:B:C:D:E=1:4.2:3.2:2.6:2$, corresponding to the population of the five iron-site groups. As a matter of fact, the dumbbell site presented the lowest decrease in the hyperfine field compared to $\text{Ce}_3\text{Fe}_{27.5}\text{Ti}_{1.5}$ (Ref. 5) and we believe that this is evidence that Cr indeed enters the dumbbell sites. The average ^{57}Fe Mössbauer field was found to be 19.2 T. This value is much lower compared to that of $\text{Ce}_3\text{Fe}_{27.5}\text{Ti}_{1.5}$, 25.3 T,⁵ as expected from the magnetic dilution of the iron sublattice due to the large number of Cr atoms substituting for Fe, with corresponding low magnetization values (Table I).

The authors are very grateful for the support and assistance provided by several researchers at the General Motors

FIG. 3. Low temperature ($T=85$ K) ^{57}Fe Mössbauer spectrum of the $\text{Ce}_3(\text{Fe,Cr})_{29}$ phase is shown along with the corresponding fit.

High field magnetization measurements of $\text{SmFe}_{11}\text{Ti}$ and $\text{SmFe}_{11}\text{TiH}_{1-\delta}$

O. Isnard, M. Guillot, S. Miraglia, and D. Fruchart

Laboratoire de Cristallographie, CNRS, BP 166, 38042 Grenoble Cedex, France and Laboratoire de Champs Magnétiques Intenses, CNRS/MPI, 38042 Grenoble, France

The magnetic properties of the ferromagnetic compounds, $\text{SmFe}_{11}\text{Ti}$ and $\text{SmFe}_{11}\text{TiH}_{1-\delta}$, which are potential candidates for high performance permanent magnets are investigated. At room temperature both compounds exhibit a uniaxial anisotropy, with the easy direction of magnetization parallel to the tetragonal axis. High field magnetization measurements up to 240 kOe in continuous fields are reported. The major changes upon hydrogen insertion are increases of the Curie temperature and of the saturation magnetization. The magnetic anisotropy constants, K_1 and K_2 , are determined and the insertion of hydrogen is found to increase K_1 . If the external field is applied perpendicular to the alignment direction, anomalous magnetization behaviors are observed in both compounds below about 150 K. The shape of this anomaly is strongly modified by the hydrogen insertion. © 1996 American Institute of Physics. [S0021-8979(96)32808-X]

INTRODUCTION

The requirements for an effective permanent magnet are good intrinsic magnetic properties, i.e., high Curie temperature, magnetization, and anisotropy field, combined with a suitable microstructure generating a high coercivity.

To fulfill these requirements, research has turned toward alloys composed mainly of the ferromagnetic 3d elements, iron or cobalt, thus leading to high magnetization and Curie temperature. Their association with rare earth elements may induce strong uniaxial anisotropy such as in SmCo_5 and $\text{Sm}_2\text{Co}_{17}$. Since the discovery of $\text{Nd}_2\text{Fe}_{14}\text{B}$, many studies have been devoted to iron-containing materials leading to a new series of intermetallic compounds among which $\text{SmFe}_{11}\text{Ti}$, $\text{Sm}_2\text{Fe}_{17}\text{N}_3$, and $\text{Sm}_2\text{Fe}_{17}\text{C}_3$ are the most promising in terms of possible permanent magnet applications. Details about the magnetism of these compounds can be found in Refs. 1–3.

In this paper we intend to probe the intrinsic magnetic properties of $\text{SmFe}_{11}\text{TiH}$ and to quantitatively analyze the effect of hydrogen insertion on the magnetic properties. This paper is organized as follows: First, we describe the sample preparation and the experimental details. Then the crystal structure is presented, the lattice parameters are analyzed, and the location of H in the cell is given. Finally, we present the magnetic characterization and discuss these results in light of earlier publications.

SAMPLE PREPARATION, EXPERIMENTAL DETAILS

The alloys have been obtained by melting the starting elements in a high frequency induction furnace equipped with a water cooled copper crucible. The homogeneity of the ingot was subsequently achieved by annealing at 950 °C for 10 days. The hydrogen insertion has been carried out under 20 bar of H_2 gas and thermal activation was needed to initiate the reaction. The structural parameters were derived from x-ray diffractometry. The x-ray patterns were recorded using a Guinier–Hägg focusing camera operated at $\text{Fe } K_\alpha$ radiation, with silicon as an internal standard. The lattice parameters have been refined, taking into account the 22 observed Bragg reflections. Thermomagnetic analysis of the sample being sealed in a silica tube to avoid oxidation or

hydrogen release, was performed using a Faraday type balance. Isothermal M vs H curves on magnetically aligned powder were carried out in a field up to 240 kOe at the High Field Facility in Grenoble.⁴ The anisotropy constants have been derived as described elsewhere.⁵

RESULTS

The x-ray diffraction pattern shows that $\text{SmFe}_{11}\text{TiH}$ retains the $I4/mmm$ symmetry of $\text{SmFe}_{11}\text{Ti}$. This result is in good agreement with earlier measurements by Zhang and Wallace.⁶ As shown in Table I the insertion of hydrogen within the crystal lattice induces a significant increase of the unit cell (about 2 Å³/H atom). This feature is quite general when hydrogen goes into intermetallic compounds and has already been observed in other series of magnetic materials such as R_2Fe_{17} (2.5 Å³/H atom) and $\text{R}_2\text{Fe}_{14}\text{B}$ (2.5 Å³/H atom).^{7,8}

We now discuss the delicate problem of the precise H content of our compound. The cell increase is found to be larger along the *c* axis of the structure than along the *a* basal plane axis. The gravimetric determination of the H concentration indicates that the H concentration is close to 1 atom per formula unit. Hence we will refer to it as $1-\delta$. The unit cell volume is slightly higher than that reported earlier⁶ probably because of a higher hydrogen content in our sample. The hydrogenation-induced increase in Curie temperature is also an indirect indication of the hydrogen concentration. Such an increase was already observed by Zhang and Wallace,⁶ but their $\text{SmFe}_{11}\text{Ti}$ hydride exhibited a lower Curie temperature confirming that the hydrogen content in our sample is higher. It may also well be that their hydrogen content was slightly overestimated.

Previous neutron diffraction studies⁹ have shown that hydrogen is located in the octahedral 2*b* site with two rare

earth and four transition metal atoms at the apexes. The complete filling of this interstitial site would lead to a maximum H concentration of one H atom per formula unit, in good agreement with the concentration determined by gravimetric methods. The exclusive filling of this interstitial site has been observed by Tomey¹⁰ in the related $\text{RFe}_{10}\text{Mo}_2$ series. This interstitial site is close to the rare earth element and hence, changes of the rare earth environment and some magnetic features are expected as will be discussed below. Finally, x-ray analysis performed on magnetically oriented powders of both $\text{SmFe}_{11}\text{Ti}$ and $\text{SmFe}_{11}\text{TiH}_{1-\delta}$ shows that, at room temperature, both compounds exhibit uniaxial anisotropy, with the easy magnetization axis parallel to the c axis of the tetragonal structure.

The magnetic features of $\text{SmFe}_{11}\text{Ti}$ and its hydride are summarized in Tables I and II. The first remarkable effect of H insertion within the lattice is an increase of the Curie temperature from 567 to 634 K. The increase of the Curie tem-

FIG. 2. Isothermal magnetization curves at 4.2 K on $\text{SmFe}_{11}\text{Ti}$ and its hydride, the field is perpendicular to the alignment direction.

perature is correlated to the increase of the exchange interaction via the increase of the interatomic distances that occurs upon insertion of hydrogen in the lattice. The increase of the ordering temperature upon hydrogenation is larger for the Sm compound than for the Gd compound ($T_C = 621$ K for $\text{GdFe}_{11}\text{Ti}$ and 652 K for $\text{GdFe}_{11}\text{TiH}$). The saturation magnetization has been obtained by extrapolation of M vs $1/H^2$. The other major change upon hydrogen insertion is an increase of the saturation magnetization at room temperature as reported in Table II. The iron sublattice magnetization itself is increased as observed on YFe_{11}Ti and $\text{RFe}_{10}\text{Mo}_2$ ($R = \text{Y, Lu}$).^{6,9,10} In Fig. 1, the room temperature magnetization curves of $\text{SmFe}_{11}\text{TiH}_{1-\delta}$ and $\text{SmFe}_{11}\text{Ti}$ are shown. The fit of the magnetization curves has been performed between 50 and 240 kOe, the difference in magnetization between the observed and calculated values is lower than 3%. This fit gave the anisotropy constants reported in Table II. The uniaxial anisotropy of $\text{SmFe}_{11}\text{Ti}$ and its hydride is confirmed by the positive value of K_1 and the K_2 value. The clear increase of the K_1 parameter reflects the strengthening of the uniaxial anisotropy by hydrogen insertion. A similar study on $\text{GdFe}_{11}\text{Ti}$ and $\text{GdFe}_{11}\text{TiH}$ where the magnetic anisotropy originates mainly from the iron sublattice shows that the K_1 remains almost unchanged at about 1.4 ± 0.1 kJ/m³ (at 300 K). These results reveal that most of the anisotropy increase observed in the Sm compound is due to an increase in the Sm sublattice contribution. The rare earth anisotropy is closely related to the electric field gradient (efg) acting on the rare earth site, a change of the efg induced by hydrogen is expected and has been checked by ¹⁵⁵Gd Mössbauer spectroscopy.¹¹ Previous results^{12,13} have shown that in the R_2Fe_{17} series hydrogen insertion induces a decrease of the rare earth contribution to anisotropy via a decrease of the efg.¹⁴ The effect of H insertion on the rare earth anisotropy appears to be opposite in the R_2Fe_{17} and RFe_{11}Ti structures

FIG. 1. Isothermal magnetization curves at 300 K on oriented $\text{SmFe}_{11}\text{Ti}$ and its hydride.

FIG. 3. Isothermal magnetization curves, at 120 K, on oriented $\text{SmFe}_{11}\text{TiH}_{1-\delta}$.

the reason for this difference may be due to a different location of H in the R neighborhood as discussed elsewhere.⁹ Finally it is worthwhile noting that N or C insertion induces a change of magnetocrystalline anisotropy opposite to that due to hydrogen. This difference is related to the nature of the interstitial element itself as already stated in Refs. 12 and 14. The increase in magnetization, ordering temperature, and magnetocrystalline anisotropy observed here make $\text{SmFe}_{11}\text{TiH}_{1-\delta}$ a potential candidate for permanent magnet applications. However its hysteresis cycle does not show significant coercivity. The magnetization curves of $\text{SmFe}_{11}\text{Ti}$ with the field applied perpendicular to the alignment direction reveal a surprising steplike behavior, as shown in Fig. 2 in good agreement with data on single crystal obtained by Kaneko *et al.*¹⁵ This agreement with single-crystal data confirms the goodness of the alignment of our powder. As evidenced by the change of slope in Fig. 2, the steplike behavior remains after hydrogen insertion but the shape of the magnetization curve is changed according to the already mentioned increase of the anisotropy. It has been shown that on $\text{SmFe}_{11}\text{Ti}$, this anomalous magnetization behavior appears below 150 K.¹⁵ We have measured the magnetization curves of $\text{SmFe}_{11}\text{TiH}_{1-\delta}$ at several temperatures between 4.2 and 300 K, and found that the magnetic transition is already present at 120 K (see Fig. 3). This curvature of the magnetization curve has already been reported by other authors^{15,16} for $\text{SmFe}_{11}\text{Ti}$ and is also present in $\text{SmFe}_{12-x}\text{Mo}_x$ compounds.¹⁷ However it is not observed¹⁸ in $\text{SmFe}_{10}\text{V}_2$, probably because of higher than second-order anisotropy terms that are known to play a major role in the $\text{RFe}_{12-x}\text{M}_x$ series. Kaneko *et al.*¹⁵ proposed that at least three *J*-multiplets are needed to explain the observed results on $\text{SmFe}_{11}\text{Ti}$. They have shown that this is not a first-order mag-

netization process as proposed earlier¹⁶ but a fast continuous rotation of the magnetic moment under the action of the external field. Furthermore, crystal electric field calculations¹⁹ performed for $\text{SmFe}_{11}\text{Ti}$ show only one minimum energy confirming this interpretation. Studying $\text{SmFe}_{12-x}\text{Mo}_x$, Kou *et al.* have obtained the same conclusion.²⁰ The same behavior may be expected for the $\text{SmFe}_{11}\text{TiH}_{1-\delta}$ compound.

CONCLUSION

Unlike what is observed for $\text{R}_2\text{Fe}_{14}\text{B}$ (Ref. 8) and R_2Fe_{17} (Ref. 14) systems, insertion of hydrogen is found to significantly increase the rare earth magnetic anisotropy of $\text{SmFe}_{11}\text{Ti}$. Using precise x-ray analysis and high field magnetization measurements, we have given a quantitative analysis of the effect of H on the magnetic anisotropy parameters, magnetization, and Curie temperature of $\text{SmFe}_{11}\text{Ti}$. For the first time, the effect of hydrogen on the anisotropy parameters K_1 and K_2 has been discussed quantitatively. Besides, we have given results on the $\text{SmFe}_{11}\text{TiH}_{1-\delta}$ solid solution with the highest reported hydrogen concentration to date. This study has evidenced that $\text{SmFe}_{11}\text{TiH}_{1-\delta}$ exhibits an anomalous behavior of the magnetization curve at low temperature. This behavior has been compared to results on other $\text{RFe}_{12-x}\text{M}_x$ compounds.

First-principles calculation of the electronic and magnetic properties of $\text{Nd}_2\text{Fe}_{17-x}\text{M}_x$ ($\text{M}=\text{Si}, \text{Ga}$) solid solutions

Ming-Zhu Huang and W. Y. Ching

Department of Physics, University of Missouri-Kansas City, Kansas City, Missouri 64110

We have studied the electronic and magnetic properties of the Si and Ga substituted $\text{Nd}_2\text{Fe}_{17}$ compounds by means of first-principles calculations. The results show that for the $\text{Nd}_2\text{Fe}_{17-x}\text{Si}_x$ ($x=1, 2, 3$, and 4) series, the total Fe moments per cell decrease as x increases but the average local Fe moments actually increase up to $x=3$, except for the 18h site which is the most preferable site for substitution. For $\text{Nd}_2\text{Fe}_{15}\text{Ga}_2$, the moments on every Fe site increase. These results are also compared with the earlier calculation on $\text{Nd}_2\text{Fe}_{17-x}\text{Al}_x$ ($x=1, 2$, and 4). From the spin-polarized density of states (DOS) and local DOS for Si, Al, and Ga, it is shown that different substituting elements can change the electronic structure of $\text{Nd}_2\text{Fe}_{17}$ crystal substantially because of the slightly different interactions with the Fe atoms, and the change in the lattice constants. Estimation of Curie temperatures based on the spin-fluctuation model shows qualitative agreement with experiments. © 1996 American Institute of Physics. [S0021-8979(96)53608-1]

Study of rare earth iron compounds R_2Fe_{17} ($\text{R}=\text{rare earth}$) of the $\text{Th}_2\text{Zn}_{17}$ type structure (rhombohedral) continues to attract a large number of researchers in the hope of raising the Curie temperature T_c to a sufficiently high level that is required for practical applications.¹⁻⁶ Other than the well known approach of doping with N or C, another promising avenue is by elemental substitution by metal or metallic ion such as Al, Si, and Ga.⁷⁻⁹ The original concept was that introduction of a metalloid atom such as Al with a larger metallic radius than Fe can lead to lattice expansion which is favorable for the ferromagnetic exchange interaction in enhancing T_c . This was the conclusion reached in the case of interstitial doping with N or C. However, in the case of Si-substituted R_2Fe_{17} compounds, it was shown that T_c increases while the unit cell volume decreases.¹⁰⁻¹³ Clearly, a simple explanation based on distance-dependent exchange interaction is not sufficient to understand the changes in magnetic properties in these compounds. Systematic calculations of the electronic structure in the substituted R_2Fe_{17} -based compounds are of fundamental importance.

We had previously reported the calculation of the electronic and magnetic properties of the Al-substituted series $\text{Nd}_2\text{Fe}_{17-x}\text{Al}_x$ ($x=0, 1, 2$, and 4) for different substituted configurations.¹⁴ Our results revealed some microscopic details of the effects of Al substitutions and were in fair agreement with experimental data available. In this article, we present a similar calculation for the $\text{Nd}_2\text{Fe}_{17-x}\text{Si}_x$ ($x=1, 2, 3$, and 4) series and also $\text{Nd}_2\text{Fe}_{15}\text{Ga}_2$. We study the concentration dependence of the magnetic moments at each site and compare the density of states (DOS) results for $\text{Nd}_2\text{Fe}_{17-x}\text{Si}_x$ ($x=1-3$), $\text{Nd}_2\text{Fe}_{15}\text{Al}_2$, and $\text{Nd}_2\text{Fe}_{15}\text{Ga}_2$ in order to understand the subtle difference due to different substitution elements. The present results have also been used to test the spin-fluctuation model^{15,16} for the calculation of T_c in this class of compounds.¹⁷

The computational procedure for the present calculation is similar to that for the $\text{Nd}_2\text{Fe}_{17-x}\text{Al}_x$ (Ref. 14) series and will not be repeated here. Basically, the first-principles orthogonalized linear combination of atomic orbitals (OLCAO) method in the local spin density approximation

(LSDA) is used to calculate the spin-polarized band structures of these compounds.^{14,18} The original rhombohedral cell (19 atoms/cell) with the experimentally measured lattice parameters was used. Experimentally, Long *et al.*¹³ and Hu *et al.*⁸ have reported neutron diffraction and or Mössbauer spectra for $\text{Nd}_2\text{Fe}_{17-x}\text{Si}_x$ ($x=0, 1, 2, 3$) and $\text{Nd}_2\text{Fe}_{15}\text{Ga}_2$. For the Si-substituted compounds, they found that Si preferentially occupies the 18h site in the $\text{Nd}_2\text{Fe}_{17}$ structure. The next preferred sites are 9d and, for $x>2$, 18f. The 6c site is completely avoided. For $\text{Nd}_2\text{Fe}_{15}\text{Ga}_2$, the most preferred substitution site is also 18h. In the present calculation, it is necessary to round the number of the substituted atoms to an integer, both for the unit cell and for the substitution site. This is a rather severe approximation and as such, quantitative agreement in the overall moments with experimental data is not expected. However, given the complexity of the system, such calculations can provide useful insights on the electronic and magnetic properties of these compounds. Accordingly, for $\text{Nd}_2\text{Fe}_{17-x}\text{Si}_x$ and for $x=1$, we replace one Fe (18h) site by a Si. For $x=2$, two cases are studied, one with two Si replacing a Fe(9d) and a Fe(18h), and the other with two Si replacing two Fe (18h). For $x=3$, we replace one Fe (18f) and two Fe (18h). And for $x=4$ Si atoms replace one Fe (18f) and three Fe (18h). In the $\text{Nd}_2\text{Fe}_{15}\text{Ga}_2$ calculation, two Fe (18h) are replaced by Ga and the Ga 3d states are treated as core states.

The results of our calculation for the site-decomposed moments are summarized in Table I. As can be seen, the moments at different sites of the same symmetry type as in the $\text{Th}_2\text{Zn}_{17}$ structure are slightly different as the result of substitution by Si or Ga. Because of the relatively large fraction of substitution, almost every Fe site will have at least one impurity atom as a nearest neighbor, especially for $x>2$. For all systems calculated we find the total magnetic moments per formula unit (excluded Nd 4f) decrease as x increases due to the dilution of the Fe lattice. However, the dependence of the average Fe moment on x for each specific symmetry site is quite different. This is shown in Fig. 1 for the $\text{Nd}_2\text{Fe}_{17-x}\text{Si}_x$ series. For $x=0$, the average Fe moments are in the decreasing order of (6c) (18f), (18h), and (9d). As

x increases, moments for the (6c) and (9d) sites show an initial increase and then saturate between $x=2$ and 3. For the (18f) site, it starts with a slower increase until it hits $x=3$ and 4 where the increase becomes more steep. The most erratic dependence is found in the (18h) site which is the preferred site of substitution. It shows some slow decrease from $x=0$ to $x=3$ but increases rapidly at $x=4$. Then at $x=4$, three of the six (18h) sites are occupied by Si and the statistical error of fluctuation can be quite large. The different Fe moments and their x dependences can be attributed to different local bonding environments of individual atoms. For example, the (6c) site with the largest moment is the so-called dumbbell site. It has one short bond connecting the dumbbells and 12 longer Fe-Fe bonds. In $\text{Nd}_2\text{Fe}_{15}\text{Si}_2$, although the short bond is only 2.38 Å, there are three bonds of 2.63 Å to the (9d) sites, six bonds of 2.77 Å to the (18f) sites, and three bonds of 2.65 Å to the (18h) sites. On the contrary, the (9d) site, which has the smallest Fe moments, has the shortest average bond lengths. It has four bonds of 2.45 Å to Fe (18f), four bonds of 2.46 Å to (18h), and one bond of 2.63 Å to (6c).

Also shown in Fig. 1 are the moments of Si and Nd (6s electrons only) which are negative, indicating slight polarization opposite the Fe moments. The degree of polarization for

Si is fairly constant as x varies and that of Nd shows a slight decrease as x increases. This is quite understandable since the polarization of the Nd 6s electrons is basically proportional to the number of Fe atoms in the crystal. For $\text{Nd}_2\text{Fe}_{15}\text{Ga}_2$, the moments on each site are quite close to $\text{Nd}_2\text{Fe}_{15}\text{Si}_2$ for the same site of substitution and show increases in Fe moments for every Fe site.

Figure 1 also shows the average moments at each symmetric site for the $\text{Nd}_2\text{Fe}_{17-x}\text{Al}_x$ series.¹⁴ Unfortunately, these earlier calculations did not include the case for $x=3$. Still, we can see the x dependence of the Fe moments are somewhat different from the $\text{Nd}_2\text{Fe}_{17-x}\text{Si}_x$ series. This is most pronounced for the (18h) site which is the most preferred site of substitution in both cases. For x from 2 to 4, the moments of the (18h) site and also the (18f) site increase much more rapidly, indicating the influence of the chemical environment on the local Fe moment. On the other hand, the dependence of the negative moments on Nd and Al on x is similar to the Si substitution.

In order to see the differences in the electronic and magnetic structures due to different substitution elements, in Fig. 2 we plot the spin-polarized DOS of $\text{Nd}_2\text{Fe}_{17}$, $\text{Nd}_2\text{Fe}_{15}\text{Al}_2$, $\text{Nd}_2\text{Fe}_{15}\text{Ga}_2$, and $\text{Nd}_2\text{Fe}_{17-1}\text{Si}_x$ ($x=1-3$). The

FIG. 1. Calculated local moments at various sites in $\text{Nd}_2\text{Fe}_{17-x}\text{Si}_x$ (left) and $\text{Nd}_2\text{Fe}_{17-x}\text{Al}_x$ (right): for $x=0$ to 4. (●) (6c); (■) (18f); (★) (18h); (△) (9d); (○) Si; (◇) (Nd).

contributions from the Nd 4f peaks are subtracted out. We can see that substitution by metal or metalloid elements in $\text{Nd}_2\text{Fe}_{17}$ leads to considerable change in the DOS. First, the total area under the occupied portion decreases due to the reduction of the 3d electrons from Fe, which has led to the reduction of the total Fe moments. Second, the main changes are in the lower part of the DOS where the interaction of the valence *p* electrons of the substituted atom with Fe 4*s* and 4*p* electrons can be significant. Third, there is a reduction in the

DOS at the Fermi level E_F , mostly in the majority spin band. These changes are quite subtle and cannot be analyzed in simple terms. In Figs. 2(b)–2(f), the blackened areas correspond to the partial DOS (PDOS) of Al, Ga, and Si, respectively. It can be seen that the three elements affect the Fe 3d band differently. For Si, the PDOS is mainly in a region below -4 eV. For Al, it moves up by at least 0.5 eV. In the case of Ga, the distribution of the Ga PDOS is more delocalized and extends toward E_F . These differences reflect the differences in the three atomic species as well as the strong site dependence in the interaction between the substituted atoms and the surrounding Fe. Si has a smaller atomic radius and four valence electrons, its bonding with nearby Fe atoms will be quite different from both Al and Ga, which have larger atomic radii and only three valence electrons. Mulliken population analysis of the calculated wave functions and overlap integrals indicate in all three cases, charge transfer from Fe atoms to the substituted ions occur.

The present results for the electronic structures of the metal-substituted $\text{Nd}_2\text{Fe}_{17}$ crystals were used to estimate the Curie temperatures in these compounds based on the spin fluctuation model of Mohn and Wohlfarth¹⁶ and the experimentally observed changes in T_c upon substitution were qualitatively accounted for (Refs. 14 and 17). The Curie temperatures for the $\text{Nd}_2\text{Fe}_{17-x}\text{Si}_x$ ($x=1,2,3$) series show the right enhancement correlation with x even though the cell volume contracts. Apparently, T_c depends more on the DOS at E_F and less on the Fe moments. This is very encouraging and demonstrates the usefulness of electronic structure theory in the study of the magnetic properties of the rare earth-based hard magnets.

This work was supported by U.S. Department of Energy under grant No. DE-FG02-84ER45170.

FIG. 2. Calculated total DOS (excluding the Nd 4f) for (a) $\text{Nd}_2\text{Fe}_{17}$; (b) $\text{Nd}_2\text{Fe}_{15}\text{Al}_2$; (c) $\text{Nd}_2\text{Fe}_{15}\text{Ga}_2$; (d) $\text{Nd}_2\text{Fe}_{16}\text{Si}_1$; (e) $\text{Nd}_2\text{Fe}_{15}\text{Si}_2$; (f) $\text{Nd}_2\text{Fe}_{14}\text{Si}_3$. Positive values correspond to the majority spin band and negative values to the minority spin band. The shaded areas in (b)–(f) are the partial DOS contributions from Si, Al, and Ga atoms, respectively.

This article presents a novel electric motor/pump system that combines an axial field, permanent magnet motor with a centrifugal pump. This system, unique because the motor permanent magnet rotor and pump impeller vanes are a single unit, provides a compact, reliable, low-noise, and high-power density electrically driven centrifugal pump suitable for underwater applications in which minimizing noise, vibration, and volume are major design objectives. Performance tradeoffs for the electromagnetic analysis were made by three-dimensional finite element analysis models in conjunction with a lumped parameter magnetic circuit model. © 1996 American Institute of Physics. [S0021-8979(96)40608-7]

I. INTRODUCTION

Because space is severely limited onboard underwater vehicles, the U.S. Navy must streamline components and systems that rob from payload capacity. The traditional electrically driven centrifugal pump set comprises an electric motor, a coupling system, and a pump [Fig. 1(a)].¹ From the perspective of the underwater application, these motor/pump sets have two major disadvantages:

- (1) low volumetric power density and
- (2) low controllability of noise and vibration.

This paper is about a tradeoff study for a new motor/pump system concept that eliminates these obstacles and promises to improve efficiency for naval underwater vehicles

[Fig. 1(b)]. The method used is three-dimensional (3D) finite element analysis (FEA) models in conjunction with the lumped magnetic circuit model.

II. INTEGRATED MOTOR/PUMP SYSTEM

The proposed integrated motor/pump system eliminates the inherent disadvantages of the traditional design. Required space is reduced because the motor stators are close to the fluid being pumped and, therefore, no auxiliary motor cooling system is necessary for high power density application. Additionally, the integrated motor/pump concept eliminates the separate coupling element (linkages and bearings), which is a primary source of failure. Vibration isolation of the motor/pump set from other components is simplified. In short, fewer system components reduces production costs, weeds out potential sources of failure, and improves reliability.

A dual air-gap, axial field permanent magnet (PM) motor² consists of a double stator with single rotor. A simplified dual air-gap, axial field PM motor is shown in Fig. 2. The rotor structure is a nonmagnetic material such as titanium with PMs; the stators are radial arrays of current-carrying conductors with appropriate end turns and connections fixed in the stator slots.

FIG. 1. (a) Traditional motor pump set and (b) exploded view of proposed integrated motor/pump system.

FIG. 2. Simplified dual-airgap, axial field PM motor.

FIG. 3. (a) Typical open impeller and (b) integrated motor/pump impeller.

The motor is configured so that the air gap between the rotor and stators is a plane perpendicular to the axis of rotation. Major PM flux crosses the air gap in the axial direction. Since the PMs must be placed with the pole faces at the air-gap surface, the air-gap flux density is proportional to the PM working flux density. Thus, using high-permanent flux density magnetic materials (such as Nd-B-Fe) is advantageous in generating high torque.

Figure 3 shows a conventional open impeller and the impeller considered in this study, which is a double-suction, radial-flow, closed impeller. Figure 4(a) is a cross section through the plane of the impeller and the stator. The impeller consists of a number of vanes attached to two backing plates. A detailed hydrodynamic analysis is being performed to determine the number and shape of the vanes required to provide a specified capacity and head for a given rotational speed. The exterior radial region of the vanes corresponding to a similar radial region of the motor stator windings is made of PM material.

Each angular sector of the impeller [Fig. 4(b)] is assigned a single magnetic polarization. Polarization alternates between adjacent sectors. The number of alternate sectors depends on the number of phases, number of magnetic poles, and the skewing angle of the impeller vane. The sizing and number of magnetic regions on the impeller are chosen to be compatible with the winding configuration of the motor stators.

III. TRADEOFF STUDY RESULTS

The electromagnetic tradeoff study used FEA 3-D models shown in Figure 5(a) in conjunction with an axial field, brushless, PM motor lumped parameter magnetic circuit model that was developed using the MathCAD spreadsheet program. Figure 5(b) shows the FEA model verification result comparing the calculated vs. measured PM field strength in air and reveals a close correlation.

FIG. 4. (a) Cross section through impeller plane and motor stator and (b) impeller vane with angular sectors.

FIG. 5. (a) FEA PM Vanes Model and (b) FEA Model Verification.

The electromagnetic tradeoff study was based on a 15-hp, 1780-rpm motor,³ for which the base specifications included a 10-inch diameter, 1-inch rotor axial thickness, 5-inch total axial length, 3-phase, 24-slot, 8-pole, and 2 mm-air-gap length.

A. Motor efficiency/SAR/number of poles

Motor efficiency decreases dramatically as the sectional area devoted to PMs decreases. Figure 6(a) shows the effect on efficiency when varying the sectional area ratio (SAR) between the PM and fluid flow area, but keeping the axial length constant (5 inches) at 10-inch diameters. Figure 6(b) shows the influence that the number of PM poles has on motor efficiency for an SAR of 50%. This result shows that there are a optimum number of PM poles in a given geometry with selected materials. In Fig. 6(c), the air-gap magnetic flux density in the axial direction is calculated for the different SARs. These results allow comparison of the magnetic flux density variation as a function of the SAR. Abrupt changes of the flux density will create large cogging force variation, which is a stray force between the stator and rotor. This result also reveals the tradeoff between the smooth operation vs. output torque or power. In Fig. 6(d), the output power (Hp) vs. motor speed was calculated for a different SAR. The result indicates that the high operational condition the losses and leakages are the dominant terms so that there are less SAR effect.

B. Rotor PM/pump vane

The shape of the vane changed as the analyses continued. Initially, wedge-shaped vanes were used, but later the vane evolved into a more hydrodynamic form to reflect the actual shape of typical impeller vanes. The rounded inner edge and sharp outer edge caused problems in modeling accuracy until the FEA model was modified to include fine meshes of elements in both these areas [Fig. 5(a)]. Figure 7 shows the rotor PM vane evolution during the electromagnetic tradeoff study using FEA. A full analysis must be per-

FIG. 6. (a) Motor efficiency vs. SAR, (b) number of poles, (c) Flux density vs. SAR, and (d) Power vs. speed.

formed to determine the most efficient vane shape from the standpoint of hydrodynamics.

C. Manufacturing and material selection

Available magnet materials for good motor electromagnetic performance have serious drawbacks as materials of construction for impeller vanes. Constructing useful and efficient impellers offers challenges. For example, the working fluid, salt water, is corrosive to many materials, and some candidate magnets are very chemically active. The vanes must be strong enough to withstand the fluid dynamic forces and centrifugal force as well as the magnetic forces of the motor.

FIG. 7. Rotor/PM vane evolution.

Some candidate magnets, however, are brittle, and some are mechanically weak. Furthermore, optimal magnetic performance dictates the magnetic gap (magnetic flux path through nonpermeable materials and salt water (or air)) be as short as possible. Any structural element (such as a stress-bearing plate) between the magnet and the stator increases the gap. In addition, if the plate is an electrically conductive material, eddy currents that diminish performance may be set up by the changing magnetic fields.

Several impeller design options seem plausible. If stresses in the impeller can be kept low, a plastic impeller, such as carbon-fiber filled PPS, may be possible. The plastic could be injection-molded around the magnets to form a single, chemically sealed unit and serve as the impeller bearing. Another option is that of hollow vanes welded (possibly by electron-beam) between two end plates. Magnet sections, previously coated for corrosion protection, are bonded in the interior of the vanes.

IV. CONCLUSION

This paper presents a novel electric motor/pump system that combines an axial field, permanent magnet motor with a centrifugal pump. Based on the tradeoff study, the authors of this paper have shown the theoretical feasibility of a new, electric motor/pump concept tailored to meet rigid design criteria for underwater systems. The tradeoffs were conducted using 3-D FEA models in conjunction with a lumped parameter magnetic circuit model. The results shows that this new concept will provide sufficient motor efficiency (up to 72% with 50% SAR) with a given geometry. More research to determine the exact vane geometry for high hydrodynamic and overall system efficiencies is planned.

Imposition of periodic magnetization patterns on high-energy-product magnetic plates

H. A. Leupold, A. S. Tilak, and E. Potenziani II

U. S. Army Research Laboratory, AMSRL-PS-PC, Fort Monmouth, New Jersey 07703-5601

Periodically magnetized permanent magnet plates with high-energy products are potentially very useful in high-field structures such as free-electron lasers, electrical machinery, and various mechanical applications such as magnetic bearings, for which they are already being used. A major problem is the lack of field sources with sufficient field amplitude to impose such patterns of magnetization on high-coercivity materials. This paper shows how such high amplitudes can be obtained for several patterns by use of modified sources of the augmented "magic ring" and "magic sphere" types. [S0021-8979(96)32908-6]

INTRODUCTION

Permanent magnet structures with a spatially periodic distribution of magnetization are commonly used in a variety of applications. Examples are in electron tubes, free electron lasers, electrical machinery, and mechanical bearings. Often these can be assembled from uniformly magnetized blocks but in some cases such as in circular bearings this is impracticable and the magnetization must be performed on one piece by an externally applied periodic field.

Both methods have drawbacks. The former involves the labor of assembly and bonding, the fragility entailed in multipiece construction, and, in the case of small pieces, wasted space needed to accommodate the binding cement. On the other hand, one-piece magnetization is difficult in high-energy permanent magnet materials because of the difficulty of obtaining sufficiently high periodic magnetizing fields especially in arrays with short periods. This paper describes novel magnetizing structures and methods whereby periodic magnetization can be effected on one-piece magnetic arrays.

ANNULAR PERIODICITY IN DISKS

Magnetic bearings sometimes take the form of pairs of annularly magnetized disks in which the magnetizations in adjacent annulae are opposite in sign. The disks are coaxially mounted so that the annulae facing each other across the air gap between them, are oppositely oriented in magnetization, thereby resulting in mutual repulsion (Fig. 1). The periodicity of magnetization fosters a degree of lateral stability.

Because such structures are exposed to large demagnetizing fields and because strong fields are required by their functions, high-energy-product materials are desirable for their manufacture. But it is the very high coercivities of these materials that militate against their full magnetization and in bearings of this type are typically magnetized to only about one-third the remanence.

To obtain periodic fields of the required peak strengths and amplitudes, we have recourse to a variation of an augmented "magic sphere" structure. Such sources are capable of delivering up to 4 T in structures of reasonable size.¹ For example, a configuration in Fig. 2(a) can produce 4 T in the equatorial slot in its iron core if its outer to inner radius ratio is about 10. If the iron core is cut into coaxial cylindrical shells separated by annular spaces of thickness equal to that

of the shells, a periodic field is produced in the equatorial slot where the to-be-magnetized bearing disk is placed [Fig. 2(b)].

Between the iron shells, the disk experiences a substantially larger field than between the spaces separating the shells. If the coercive force of the disk lies between the maximum and minimum fields, corrected for demagnetization (correction typically of the order of 5–10 kOe), it will be fully magnetized where the field is maximum and only partially magnetized at the field minima. The resulting pattern is illustrated by the qualitative sketch of Fig. 3(a).

The disk is then placed into a similar magnetizing fixture in which the pattern of iron cylinders is radially displaced by one-half period with respect to that in the original fixture so that the positions of the maxima and minima are interchanged. Also the disk is oriented opposite to its position during the original magnetization. Then the field minima are applied to where the magnetization of the disk is maximum

FIG. 1. (A) Top view of the disk with periodic, annular magnetization. (B) Diametric sectional view of disks mounted in opposition to form a levitated bearing.

FIG. 2. Cross sections of magic sphere variants. (A) The augmented "magic sphere" consists of magic sphere field sources (a), an iron spherical core (b), and an equatorial slot (c). (B) The augmented magic sphere with an iron core cut into annular cylindrical shells (a) and center rod (b). Solid arrows indicate magnetization of permanent magnets; dotted arrows that of passive materials such as iron.

and the field is insufficient to substantially diminish it. On the other hand, the field maxima are where the magnetization of the sample is much weaker and therefore easily reversed and fully magnetized in the opposite direction. The result is the fully aligned periodic magnetization pattern of Fig. 3(b).

Figure 4 shows the maximum and minimum fields in a seven period iron sphere core as a function of the field applied by the "magic sphere." For convenience, the abscissa of the plot is the outer to inner radius sphere ratio (r_o/r_i) rather than the applied field itself which is given by²

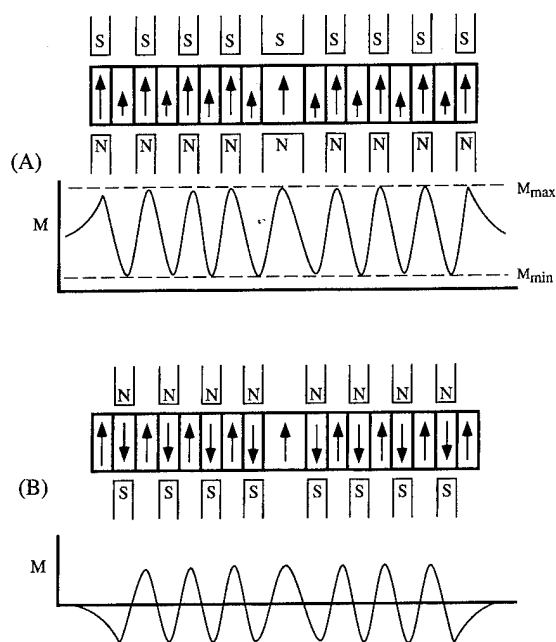

FIG. 3. Magnetization of the disk. (A) The disk is placed in a slot between annular iron shells marked N and S. The resulting magnetization pattern is shown by arrow lengths in disk and by the accompanying qualitative graph. (B) The disk is placed in a second slot with the opposite field sense and with iron shells displaced by one-half period with respect to (A). The graph and arrows show a complete reversal of the weakly magnetized areas of (A) and full magnetization in the new direction while the originally fully magnetized areas of (A) are unaffected.

FIG. 4. Fields in equatorial slot of annular periodic magnetizer: — is maximum, --- is minimum. The data are for a slot diameter of 4 cm and a slot width of 0.15 cm. The "magic sphere" material has a remanence of 1.2 T and the seven cylindrical shells in the core are of Hyperco 50.

$$B = (4/3)B_r \ln(r_o/r_i), \quad (1)$$

where B_r is the remanence of the magic sphere material.

Unfortunately, the field amplitude decreases while the magnetizing field grows with increasing applied field. This means that while larger spheres gain accessibility to higher coercive forces, their flexibility with regard to broad coercivities is not as good. Nevertheless, their range of usefulness extends over most of the $\text{Sm}_2\text{Co}_{17}$ materials, including the frequently used temperature compensated varieties.³

Applied fields can be made adjustable by the circumscription of hemispherical shells of increasing radius about the core sphere. Alternatively, adjustable magic spheres such as those described in Ref. 4 could be employed.

To prevent exposure of the disk to erratic magnetization sequences, the magnetization processes should be effected by a jig that contains the upper and lower hemispheres of the magic spheres with their cores. These would be made to converge on the disk in a controlled fashion by a motorized contrivance on the jig. This is necessary because of the large attractive forces that grow between the hemispheres as they approach each other.

RECTILINEAR PERIODICITY ON PARALLELEPIPEDS

Similar techniques can be used to impose periodic magnetized striations upon rectangular strips (Fig. 5). In such cases, the magnetization would be accomplished by an augmented magic cylinder.² Two such strips facing each other across a gap would constitute a simple free-electron laser or wiggler. Strips of iron covering the outer surfaces of these periodic strips would form a flux return path and augment the periodic field in the gap (Fig. 6).

AXIAL FIELD AZIMUTHAL PERIODICITY

The iron core of an augmented magic sphere can be cut into wedges whose vertices meet on the sphere's polar axis. If alternate wedges are removed, an azimuthally periodic field results in the equatorial slot. This field can then be used to impose an azimuthal pattern on a disk by the successive

FIG. 5. Half-section of the rectilinear periodic magnetizer; (a) permanent magnet "magic ring;" (b) iron irises, (c) slot for the magnetized bar (d) which emerges with the magnetic pattern shown. As in Fig. 3, the bar must be inverted and moved one-half period along the magic ring axis to obtain the desired pattern.

method of the previous section. The periodic field of the magnetizing structure could also act simultaneously as a wiggler field and as the field confining the charged particles to the desired circular path.

RADIAL FIELD AZIMUTHAL PERIODICITY

The iron core of the magnetizing devices of the previous section can be used to produce an azimuthally periodic radial magnetization pattern on an annular ring rather than an axial one on a disk. Such rings form the stator or rotor in electrical machinery and in circular-trajectory, free-electron lasers where the particle oscillation is in the axial, rather than the radial, direction. This is done by eliminating the equatorial work slot and placing the core in the central cavity of a

FIG. 6. Wiggler formed from two rectangular strips magnetized in the apparatus of Fig. 5. The shaded outer strips form an iron flux return path.

FIG. 7. Structures for the production of azimuthal periodicity of (a) the axial field, (b) the radial field. The latter is indicated by the flat arrows through element c.

sphere formed by two magic hemispheres placed in the opposition. The flux in such a structure would be squeezed radially outward (or inward) in the equatorial plane. The flux density would be greatest in the radial paths in the iron wedges and least in the space between them as in Fig. 7(B). The ring to be magnetized would then be placed in an equatorial annular space in the vicinity of the boundary between the magic sphere and its inner cavity. Other, possibly more efficient iron core structures could also be used in lieu of the spherical wedges described in the preceding paragraphs.

A second magnetization with the ring displaced by one-half period with respect to the magnetizing core would complete the desired magnetic array as in all of the other cases discussed.

Napier University, 219 Colinton Road, Edinburgh EH14 1DJ, United Kingdom

The article reports on a study of the effects of slot closure in axial-field permanent magnet brushless machines by a two-dimensional finite element method (2D FEM) of analysis. The closure of the slots is made by using soft magnetic powder wedge material. Parameter values and machine performance for the open and closed slot configuration are computed. In order to test the 2D FEM model, calculated results are compared with measurements and favorable agreement is shown. © 1995 American Institute of Physics. [S0021-8979(96)05608-1]

I. INTRODUCTION

The shape of the slot head in electrical machines has an important bearing on the high frequency stator losses which can be induced. Many electrical machines are easier to wind if the slots are open. However, they cause flux pulsations in the air gap of the machine. As a compromise, wedges which saturate are frequently employed. These can be difficult to manufacture because the flux is not unidirectional. A good solution is to use powdered composite slot wedge materials.¹ These effectively close off the slot magnetically and so reduce the perturbation to the flux in the air gap.

The particular machine described in this article is an axial field of permanent magnet disk type. Axial field disk machines^{2,3} have important applications in the drive systems of electric vehicles, particularly from the point of view of directly driving the rear wheels of the vehicle. Such machines are difficult to produce with semiclosed slots because there are no individual laminations which can be stamped—the core is formed from a continuous strip (coil) of lamina-

tion material, and it is much easier to simply mill a parallel sided slot through the toroidal coil. This also makes it much simpler to insert the winding. Hence these machines present a particularly suitable application for powder core wedges.

By employing closed slots in a machine, the ripple flux in the air gap and the pulsating tooth flux can be reduced; also cogging torque and iron losses are diminished, and as a consequence vibration, noise, and efficiency are improved. On the other hand, the closure of the slot produces a decrease in the rotor magnetic field which is linked with the stator winding and an increase of self- and mutual inductances of the phases of the motor.

II. TWO-DIMENSIONAL FINITE ELEMENT METHOD

It is known that the structure of this machine generally requires three-dimensional modeling for accurate analysis—however, the two-dimensional (2D) method adopted here is shown to give good results.

From the symmetry of the magnetic structure, the boundary conditions represented in Fig. 1 are adopted and only one stator and a half of the rotor need to be modeled; moreover, periodic conditions allow us to reduce the problem to a quarter of the machine (one pole pair). The analysis method adopted here has been to introduce a notional radial

FIG. 1. Boundary conditions (p is the number of pole pairs).

FIG. 2. Front view showing the notional radial cut.

FIG. 3. Air gap flux density distribution.

FIG. 6. Load flux line distribution.

FIG. 4. Air gap flux density distribution along the external segment (segment 1).

FIG. 7. Tooth-induced emf vs time with open and closed slots.

FIG. 5. No-load flux line distribution.

FIG. 8. Phase self-inductance with open and closed slots.

FIG. 9. Phase to phase mutual inductance with open and closed slots.

cut through the stator (Fig. 2) and open the machine out into a linear form. In this article a four-segment model is used.

In order to test the 2D finite element method (FEM) multisegment model, calculated results and measurements are compared for the open slot machine. The computed local quantity—air gap field density distribution around the stator, is found to be very close to the measured value obtained by Gaussmeter measurement (Fig. 3).

III. SLOT CLOSURE BY WEDGE MATERIAL

The use of closed slots results in a reduction of the permeance variations due to the slot openings. This effect can be observed on the wave form of the air gap flux density (Fig. 4) where a very smooth distribution occurs. The contrast in magnetic behavior in the core and air gap between an open and closed slot machine is shown in Figs. 5 and 6, where no-load and load flux line distributions are drawn.

Furthermore, the efficiency improvement in the closed slot design can be tested using a method based on the evaluation of the induced emf per stator tooth due to the rotation of the rotor permanent magnets. This technique has already been used on other types of electrical machines, e.g., asynchronous and radial field brushless motors. This wave form of stator tooth induced emf can be directly related to the teeth and yoke eddy current iron core losses, and for this reason, the tooth-induced emf wave form assumes a very important meaning.

FIG. 10. λ - i characteristics for closed and open slot motors.

In Fig. 7, the measured induced emf wave forms are compared for the open and closed slot motor. It should be noted that the closed slot motor has a smaller induced emf ripple and thus smaller iron losses than the motor with open slots.

Unfortunately, the closed slot design results in lower values of phase induced emf since less flux will link the stator conductors, and so result in a slight reduction of the maximum torque provided by the motor.

Furthermore, another important effect due to the closure of the slots can be observed on the self- and mutual inductances. An inspection of these machine parameters reveals that the motor with closed slots possesses greater inductance(s) than the motor with open slots (Figs. 8 and 9).

Moreover, from Figs. 8 and 9 it will be observed that the second-order harmonics of self- and mutual inductances do not change while their average values change markedly, i.e., the percentage values of second-order harmonics of self- and mutual inductances referred to average values are reduced. In the closed slot design, the increase in the inductance values can be attributed to the higher permeance of the magnetic circuit. λ - i profiles shown in Fig. 10. If the saturation level is not high, the magnetic behavior points lie on the linear segment of the magnetic characteristic (point A on the open slot magnetic curve and point B on the closed slot magnetic curve). Moreover, at these points the apparent inductance (λ/i) and incremental inductance ($d\lambda/di$) are equal.⁶ Accordingly, the closed slot inductances are greater than the open slot inductances because the closed slot magnetic curve slope is greater than that with open slots. On the contrary, if the saturation level is high and so the behavior point lies on the nonlinear zone of the magnetic characteristic, it is necessary to distinguish between apparent and incremental inductance. In particular, when the open slot magnetic behavior point lies on the nonlinear zone of the magnetic characteristic (point C), the closure of the slots produces a decrement of the slope around the behavior point (point D) and therefore gives rise to incremental self- and mutual inductances.

IV. CONCLUSIONS

The article describes the effects of slot closure using soft magnetic powder wedge material in axial-field permanent magnet brushless machines. The analysis has been performed by a 2D FEM procedure. The method adopted here has been to introduce a notional radial cut through the stator and open the machine out into a linear form. A previous test of the model shows a favorable agreement between calculated and measured results. The effect of the closure of the slots on the air gap field distribution and on the tooth-induced emf produce an improvement in the motor behavior. In particular the reduction of the air gap flux density ripple reduces unwanted effects like vibration, noise, and iron losses in the stator teeth.

An efficient design to reduce the flux leakage of a spindle motor

T. F. Ying, C. M. Chen, C. P. Liao, M. D. Wu, and D. R. Huang

Opto-Electronics & System Laboratory, ITRI, Chutung, Hsinchu, Taiwan, Republic of China

A small dc brushless spindle motor with small magnetic flux leakage must be used for a CD-ROM drive application because the magnetic flux leakage may affect the magnetic and electric control circuit of the pickup head. This paper presents a motor design that efficiently reduces magnetic flux leakage by using a pair of yokes on the rotor magnet. Using these yokes at a distance of 2.0 mm reduced the magnetic flux leakage from 344 to 29 G along the radial direction and from 117 to 10 G along the axial direction. After shielding for the magnetic flux leakage, the dynamic performance of the motor cannot be affected. The torque of the CD-ROM spindle motor can be controlled at the same range for shielded and unshielded spindle motors. © 1996 American Institute of Physics. [S0021-8979(96)33008-0]

INTRODUCTION

A CD-ROM drive application requires a spindle motor with a high-rotating torque to reach quick access time. The rotating torque of a spindle motor can be increased by using the rare-earth magnet, which has a high magnetic energy product, but the magnetic flux leakage caused by these magnets is also increased and thus affects the pickup accuracy of the optic head of the CD-ROM drive. The purpose of this research was to develop an efficient shielding design to reduce the flux leakage that is induced by a pair of rare-earth magnets in a CD-ROM spindle motor.

EXPERIMENTS

In an effort to design a compact, efficient motor for a suitable high speed CD-ROM drive application, this laboratory developed a coreless axial spindle motor. The motor has six coils and is driven by a three-phase switching circuit. The rotor magnet, magnetized in the axial direction with eight poles, is made of a ring-shaped NdFeB with $(BH)_{\max} = 36$ MG Oe. Because the magnetic circuit of this axial spindle motor is formed as a magnetic circuit open loop, the magnetic flux leakage that occurs around the magnets cannot be ignored. The value of flux leakage depends significantly on the different positions of the motor and the distance of measured points from the magnets. Figure 1 shows the structure of a spindle motor without shielding. The x_1 , x_2 , x_3 , and x_4 represent the different positions of the magnet and are used to measure the flux leakage at each fixed distance interval of 0.4 mm along the radial direction. y_1 and y_2 are also used to measure the flux leakage at each distance interval of 0.2 mm along the axial direction. To improve the efficiency of the spindle motor for a CD-ROM drive, a pair of shielding yokes made of carbon steel is used to cover the magnets as shown in Fig. 2. The radial thickness of the yoke, expressed as (l) , and the axial thickness, expressed as (m) , are 0.8 and 1.0 mm, respectively. The magnetic profiles of the magnets and the leakage of magnetic flux density in both the radial and axial directions from the rotor magnets were measured by using a Hall probe that was connected to a Gauss meter at a different position.¹ The leakage of magnetic flux can be used to evaluate the efficiency for the magnetic shielding design of the spindle motor.

RESULTS AND DISCUSSION

Figure 3 shows the magnetic field profile and flux density of a single rotor magnet. The axial magnetic flux density on the surface of each magnet is about 4400 G. If the gap between the two rotor magnets is 3 mm, the maximum magnetic flux density measured between these two magnets can be increased from 4400 to 5500 G as shown in Fig. 4. The increase of magnetic field strength in this motor with two rotor magnets can also increase the leakage of magnetic flux outside the motor. The measured magnetic flux leakage for an unshielded motor at positions of x_1 , x_2 , x_3 , and x_4 are shown in Fig. 5. The maximum value of the magnetic flux leakage occurred on the surface of the magnet at the x_2 position and is about 2319 G. The testing values of flux leakage at the distance of 2.0 mm from the surface of the magnet at reference positions of x_1 , x_2 , x_3 , and x_4 on the magnet surface are 34, 344, 306, and 19 G, respectively. The measured values for a shield motor are plotted in Fig. 6. The maximum value that occurred at the same position on x_2 is reduced to 412 G. When the distance is 2.0 mm from the magnet, the values of x_1 , x_2 , x_3 , and x_4 are 7, 29, 5, and 2 G, respectively.

The measured values of the flux leakage along the axial direction for a spindle motor without shielding on y_1 and y_2 are shown in Fig. 7. The maximum value of these data is about 549 G occurred around the position y_2 . To reduce the magnetic flux leakage from these two magnets, a plate was

FIG. 1. The structure of the spindle motor without shading yoke.

FIG. 8. The magnetic flux leakage distribution along the axial direction with an unshaded condition.

attached to each magnet as a backyoke for the original motor design.² Using a backyoke configuration has the same effect as magnetic shielding. The maximum value leaked from each magnet is much less than the 4400 G that was measured on the magnet surface. At the axial distance of 2 mm from the position of y_1 and y_2 , the magnetic flux leakage is about 112 and 117 G, respectively. As shown in Fig. 8, the flux leakage is reduced markedly by using the shielding yoke. The leakage values are reduced from 112 and 117 G to 9 and 10 G, respectively.

The magnetic field between the two magnets measured along the radial distance 11 mm extended from the shaft of the motor to the outside of the motor is shown in Fig. 9. The interaction area of coils and magnets is in the area between 6 mm from the shaft and 11 mm from the shaft along the radial direction. Curve 1 shows the magnetic field distribution without shielding. After shielding yokes were added to the magnets, the magnetic field profile changed and is shown as curve 2. The magnetic circuit is changed by using the shielding yoke. When the spindle motor is shielded, the magnetic flux density acting on coils is increased in the inner area between magnetic poles and decrease in the outer area between magnetic poles. It is clear that the magnetic field of the motor with shielding yokes decays markedly compared to the motor without shielding yokes. Good magnetic shielding design for a motor application should not affect the dy-

FIG. 9. The magnetic flux density distribution between two magnets.

FIG. 10. The $T-N$ curve of the spindle motor.

namic performance of the motor. The $T-N$ curve expressing the relation between rotation torque and speed is usually used to evaluate the dynamic characteristic of the motor. The testing results of the $T-N$ relation for a shielded and an unshielded condition are shown in Fig. 10. Curve 1 expresses the unshielded condition, and curve 2 expresses the shielded condition. These two curves are almost the same, and the shielding design does not affect the dynamic characteristic of this spindle motor.

The mass of these yokes is about 3.9 g and the extra moment inertia caused by these yokes is about 6.1 g cm^2 compared with the nonshielding condition. For a CD-ROM drive application, the inertial moment produced by a disk with a diameter of 12 cm loaded on the spindle motor is about 292.5 g cm^2 . The value of 6.1 g cm^2 is much less than 292.5 g cm^2 , and obviously it cannot affect the relation of $T-N$. It is another matter why the dynamic performance was not affected by the shielding design. According to the test result shown as Fig. 9, the magnetic flux density of the motor with shielded yokes acting on coils is always more than that of the motor without shielding yokes. Because the stronger magnetic field acting on coils for a shielded condition is eliminated by the extra moment inertia caused by shielding yokes, the $T-N$ relation remains almost the same for these two different conditions (see Figs. 9 and 10).

CONCLUSION

The magnetic flux leakage acting on the pickup head in a CD-ROM drive application can be effectively reduced by using a shielding design of a pair of yokes on the rotor magnets of the spindle motor. The $T-N$ curves of the axial spindle motor show that the dynamic characteristic of rotation is almost not affected by the extra moment inertia produced by the shielding yokes. According to the results of this research, the magnetic flux leakage of a high-torque spindle motor can be reduced efficiently for a CD-ROM drive application.

Magnetic profiles of bonded magnets affected by the magnetizing fixtures

Donyau Chiang, Shyh-Jier Wang, and Der-Ray Huang
Opto-Electronics & System Laboratory ITRI, Hsinchu, Taiwan, Republic of China

The four-pole magnetic profiles of the bonded magnets can be obtained by using planar and circular magnetizing fixtures with and without iron backyokes. With the aid of an iron fixture and iron backyoke, the bonded magnets are easily saturated with a shallow saddle profile in each pole. The saturation voltage is about 400 V for a 1600 μF magnetizer. From a practical point of view, it is better to use the planar fixture than to use the circular fixture. © 1996 American Institute of Physics. [S0021-8979(96)33108-7]

I. INTRODUCTION

The multipole bonded magnet containing Sr-ferrite has been widely used in fan motors as a rotor part. In the design of a fan motor with good performance, a ring magnet with high magnetic strength and optimized magnetic profile to match the stator is one of the dominant components. The magnetic profiles strongly depend on the geometry and material used for the magnetizing fixture. Huang *et al.*¹ used a two-pole fixture to magnetize melt-spun Nd-Fe-B bonded magnets. They found that the magnetic profile is dependent on the fixture geometry. Nakada and Takahashi² calculated the effects of magnetic pattern on the torque in a brushless dc motor. They concluded that the magnetic wave forms necessary for high torque are, in increasing order, cosine, trapezoidal, and square wave. In this paper, we demonstrate the effects of planar and circular magnetizing fixtures on the magnetic profile of rubber bonded magnets. Finite element method (FEM) analysis is used to explain the magnetic patterns.

II. EXPERIMENTAL DETAIL

The rubber bonded magnets containing strontium-ferrite were used in this study. The dimensions of the magnets were 57 mm long by 5.1 mm wide by 1.4 mm thick. The magnetic characteristics determined by a vibrating sample magnetometer at 24.6 °C were $B_r=2336$ G, $bH_c=1965$ Oe, $iH_c=2322$ Oe, and $BH_{\max}=1.4$ MG Oe, respectively. The geometric features of the magnetizing fixtures and backyokes for the four-pole magnetization are shown in Fig. 1. Two turns of the magnetizing wires with 1.2 mm diam, expressed by the shaded circles in Fig. 1, were wound into each slot for the planar fixture and into the 4.8-mm-diam slot for the circular fixture. Epoxy with high dielectric strength was forced into the space between the slot and wires to prevent wire vibration during the magnetization process. Both magnetizing fixtures and backyokes were made of soft iron and designed to fit the bonded magnet length. The magnetizer was of 1600 μF charge capacity and the applied magnetizing voltages ranged from 300 to 1100 V. The strip magnets were laid on the plate when using the planar fixture and were wound around the fixture when using the circular fixture. We magnetized the bonded magnets with or without the backyokes on them. The peak currents for each magnetization were recorded by a peak current meter. The peak currents for different magnetization conditions are listed in Table I. In general, the currents required for circular fixtures are higher

than that for planar fixtures. In each case, there is no significant difference in the current when measured with and without a yoke. After magnetization, the magnet was wound to the shape of a ring and inserted into an iron hollow cylinder. The magnetic profiles of the magnetized magnets were measured by an automatic magnetic measurement system.³ The distance between the probe sensor and the magnet surface was kept at 0.5 mm. This measuring system was mainly comprised of a gaussmeter, a stepping motor with its controlling unit, and a data acquisition unit. The collected data could be displayed on the screen and printed out immediately. We could also retrieve the data files and do further data operation.

III. FINITE ELEMENT METHOD SIMULATION

Finite element method (FEM) simulation is a useful method for predicting the magnetic profile of the magnetiz-

1100	8.5	8.5	9.5	9.4

ing fixture before the fixture design is fabricated. The magnetic patterns calculated by FEM for various geometric features of the fixture are used as a data base which can help reduce the trial and error during the design period. The FEM used in this study was MagNet 5.1 licensed from Inforlytica Co. The magnetic profiles calculated for the circular fixture without a backyoke at applied voltages of 400, 700, and 1100 V are shown in Fig. 2. The geometric features and applied currents are given in Fig. 1(c) and Table I, respectively. The profile in each pole is saddle shaped and the magnetic strengths increase with increasing voltage.

IV. EXPERIMENTAL RESULTS AND DISCUSSIONS

Figure 3 shows the measured profiles when the magnets were magnetized by using a circular iron fixture without a backyoke. The saddle pattern in each pole has a deep valley. The result is comparable to that obtained from the FEM calculation. The coercive force measured for the bonded magnet is 2000 Oe. Empirically, a magnetic strength of three times the coercive force is required to saturate the magnet. From the FEM simulation, a voltage of 700 V is a threshold voltage to bring the magnet saturation in peak position. The maximum peak strengths when magnetized at 700 V are nearly equal to those for 1100 V as depicted in Fig. 3. The

FIG. 2. FEM simulation for a circular iron fixture without backyoke. The applied voltages are 400 V (1), 700 V (2), and 1100 V (3).

FIG. 3. Magnetic profiles obtained by using the circular iron fixture without an iron backyoke. The applied voltages are 400 V (1), 700 V (2), and 1100 V (3).

magnetic valley strength strongly depends on the magnetizing voltages and the strength increases with increasing applied voltages. The absolute values of magnetic valley strength averaged for 400, 700, and 1100 V are 275, 553, and 628 G, respectively. The peak strengths are 602, 678, and 712 G corresponding to applied voltages of 400, 700, and 1100 V.

The magnetic profiles of the magnets magnetized by a circular fixture with an iron backyoke are depicted in Fig. 4. The saddle shape for each pole is shallow compared to the deep saddle shape obtained by magnetization without the backyoke. The three curves measured for magnetizing voltages of 400, 700, and 900 V, coincide. The bonded magnets approach saturation at 400 V and magnetizing voltages over 400 V have no significant effect on magnetic strengths. The absolute value of magnetic strength in each pole averaged for the three applied voltages is 758 G at the peak position and 626 G at the valley position. The standard deviation is ± 40 G for 15 measurements. In Fig. 4, the traces for the three

FIG. 4. The magnetic profiles obtained using the circular iron fixture with an iron backyoke. The applied magnetizing voltages are 400, 700, and 900 V.

FIG. 5. The magnetic profiles after magnetization by planar fixture with a backyoke. The applied voltages are 400, 700, and 1100 V.

magnetizing voltages do not coincide exactly. Some portion of the deviation may come from inhomogeneous mixing of the ferrite, and from unequal angular separation of poles. The unequal angular separation results from the limited space available for bending the magnetizing wires and the nonuniform distribution of wires embedded in the fixture slots.

The magnetic profiles of the magnets magnetized by a planar fixture with an iron backyoke are depicted in Fig. 5. The profile shows a shallow saddle shape in each pole, similar that obtained when magnetized by a circular fixture. Because of the intimacy between the magnetizing wires and the fixture slots, the three measured curves for magnets magnetized at 400, 700, and 1100 V are more consistent than those obtained by using the circular fixture. With the help of the backyoke, the bonded magnets saturate at 400 V. The absolute value of magnetic strength averaged for the three applied voltages is 735 G at the peak position and 610 G at the valley position. Again, some portion of the deviation between curves comes from the ferrite inhomogeneity. Typically, the inhomogeneous mixing of ferrite in the bonded magnets can cause ± 27 G deviation from the averaged values measured

FIG. 6. Magnetization profiles after using a planar fixture without an iron backyoke. The applied voltages shown here are 400 V (1), 700 V (2), and 1100 V (3).

FIG. 7. The magnetic peak strengths and valley strengths vs number of cycles of winding and stretching. No significant difference is observed after 800 winding and stretching cycles.

from 15 measurements. Because the magnets are easily handled when using the planar fixture, there is a practical advantage to use the planar fixture for mass production.

Figure 6 shows the measured profiles when the magnets were magnetized by using the planar iron fixture without an iron backyoke. The saddle pattern, similar to Fig. 3, has a deep valley at each pole in contrast to a shallow valley in Fig. 5. The average absolute values of magnetic strength at the valley position for 400, 700, and 1100 V are 215, 481, and 602 G, respectively. However, the magnetic strengths at the peak positions are approximately equal to each other. The average maximum is 730 G which is close to the 735 G obtained when using a backyoke. Magnetizing voltages of 1100 V or above are needed to saturate the bonded magnet when magnetized using the planar iron fixture without an iron backyoke.

An important point for the practical use of these magnets is that there should be no magnetic degradation when winding the magnetized strip into a ring. To examine this point, a magnet magnetized at 900 V was repeatedly wound and stretched and the magnetic profile was recorded. Figure 7 shows the result. Both peak and valley field values are located around their average values within the experimental error of about ± 10 G. The magnets show no magnetic degradation after 800 repeat windings and stretchings.

A. Mitsis

Department of Physics-Chemistry, TEI of Pireaus, 122 44, Athens, Greece

Mould injection $\text{Nd}_2\text{Fe}_{14}\text{B}$ magnetic material of density $\rho \sim 4$ g/cc and of an energy product $(\text{BH})_{\text{max}} \sim 4$ MGOe, has been pressed into the form of cylindrical segments in order to investigate the possibility of preparing cylindrical magnetic multipoles which could be used as magnetic gears. The obtained cylindrical bonded magnet segments have a length of 3 cm and an angle width of $\varphi = 90^\circ$ or $\varphi = 45^\circ$. These segments are easily magnetized along a radial direction at the angle $\varphi/2$, using a conventional electromagnet at a magnetic field of 2 T. Subsequently, the opposite magnetized segments are combined and bonded together with ultrasonic technique. The final result of the above procedure is the formation of a magnetic multipole cylinder which could be used as a magnetic gear. Here, except the preparation technique, we report the maximum torque applied versus the magnetization M of the poles and the distance between the gears. The dependence of the applied torque on the rotational frequency is also examined. © 1996 American Institute of Physics. [S0021-8979(96)65108-1]

Structure and magnetic moment of α'' -Fe₁₆N₂ compound films: Effect of Co and H on phase formation (invited)

Migaku Takahashi, H. Takahashi, H. Nashi, H. Shoji, and T. Wakiyama
Electronic Engng., Tohoku University, Sendai 980-77, Japan

M. Kuwabara
Kobe Steel USA Inc., Palo Alto, California 94304

In order to determine the intrinsic value of magnetic moment, σ_s , of α'' -Fe₁₆N₂ compound, the magnetic moment of $(\alpha'' + \alpha')$ -Fe₁₆N₂ films is discussed in connection with the degree of N site ordering in nitrogen-martensite. To establish the more general relation between Fe-N martensite structure and σ_s , the Fe-N system is expanded to Fe-Co-N and Fe-H-N systems. As a result, it is found that (1) The existence of completely the same structure as bulk α'' phase was reconfirmed even in the film form by the precise structural analysis using x-ray diffraction, transmission electron microscopy and Mössbauer analysis, (2) Fe-H martensite was synthesized by using sputtering under Ar+H₂ atmosphere, (3) Stable formation of α'' -(Fe_{100-X}Co_X)₁₆N₂ ($X=10-30$) phase through N site ordering by postannealing is proposed to be fairly difficult due to the sudden decrement of the phase decomposition temperature, $T_{p.d.}$, of α' -(Fe_{100-X}Co_X)-N ($X=0-30$). $T_{p.d.}$ of α' -(Fe_{100-X}Co_X)-N ($X=0-30$) phase decreases from 200 °C to RT with increasing Co and N contents, and (4) The intrinsic value of saturation magnetization of the α'' -Fe₁₆N₂ phase is convinced to be no more than 240 emu/g ($\approx 2.4 \mu_B$ per Fe atom on average) at 300 K. © 1996 American Institute of Physics. [S0021-8979(96)15508-9]

I. INTRODUCTION

"Giant Moment or Not" in α'' -Fe₁₆N₂ compound, which is initially proposed by the present authors¹⁻³ and Coey's group^{4,5} against the original report by Kim and Takahashi⁶ in 1972, caused a great sensation in magnetism. Some experimentalists still believe the appearance of giant magnetic moment about 2.9T⁷⁻⁹ in this compound. However, the experimentally proposed values of magnetic moment, σ_s , in α'' -Fe₁₆N₂ phase by various research groups vary widely from 240 to 315 emu/g.¹⁻¹¹ Therefore, many magneticians, including theoreticians, have wondered whether one is looking "at revolutionary results or egregious errors."⁴

This physically chaotic situation of σ_s is mainly caused by (1) ambiguity in phase identification of α'' -Fe₁₆N₂ compound, (2) The unreliable method for fixing the volume fraction of α'' phase in whole films, and (3) lack of exactness in the values of σ_s for other Fe nitrided phases (γ' -Fe₄N and γ -austenite) used in the calculation to determine the σ_s of the α'' -Fe₁₆N₂ phase.

In order to determine the exact σ_s of α'' phase without any ambiguity, Fe nitrided films consisting of α'' single phase are essentially required. From this standing point of view, present authors have developed the precise experiments to synthesize α'' -Fe₁₆N₂ single phase film (without the α' -Fe₁₆N₂ phase).^{1-3,12-14} For reliable phase identification, a transmission electron microscopy (TEM) experiment is carried out to ensure the lattice constants and the crystal morphology of the α'' -Fe₁₆N₂ phase which have been already recognized by former x-ray diffraction (XRD) experiment.¹⁻³ Furthermore, in order to make clear the more precise environment of Fe atoms in body-centered-tetragonal (bct) struc-

ture, Mössbauer analysis was also carried out to detect three hyperfine field interactions due to three different Fe sites in bct lattice.

While, for determination of σ_s of α'' -Fe₁₆N₂ phase by using the net value of σ_s of whole films consisting of a phase mixture, the exact volume fraction of the α'' phase in whole films should be necessary. Up to now, for the estimation of the volume fraction of α'' phase in whole samples, Wallace *et al.*⁸ simply adapted the XRD analysis, Gao *et al.* adapted statistical single grain nano probe electron diffraction analysis⁹ and the others^{1-3,5,10,14} used Mössbauer analysis. However, XRD analysis, which probes the surface region of the powder sample, is considered unsuitable for this purpose. Especially, for films, preferred grain orientation of the films disturb the exact derivation of the volume fraction of α'' phase in the whole films. On the other hand, Mössbauer analysis, which probes all environment of Fe atoms in the films, is more suitable for this estimation. In our study,³ to determine the exact volume fraction of the $(\alpha' + \alpha'')$ -Fe₁₆N₂ phase in the whole film, successive experiments of conversion electron Mössbauer analysis was carried out. Through the systematic experimental results mentioned above, we concluded that the intrinsic saturation magnetic moment in α'' -Fe₁₆N₂ phase should be no more than 240 emu/g.¹⁻³

In the present study, in order to see the more general relation between Fe-N martensite structure and σ_s , the Fe-N system is expanded to Fe-Co-N and Fe-H-N systems.

Based on the results for the various nitrogen martensites, the magnetic moment of α'' -Fe₁₆N₂ films is discussed in connection with the change of unit-cell volume of the bct struc-

FIG. 1. X-ray diffraction patterns for the Fe-N films fabricated under different N_2 flow ratio (after annealing 150°C for 2 h.).

ture and the degree of N site ordering in nitrogen martensite.

II. EXPERIMENTAL PROCEDURE

The precise experimental conditions for film fabrication, structure analysis, and magnetization measurement are given in the previously reported articles.^{1-3,15}

A. Phase formation

1. α' , α'' - Fe_{16}N_2 films

In Fig. 1, typical changes of XRD patterns of the films prepared under $P_{\text{total}}=10$ m Torr, deposition rate= $240 \text{ \AA}/\text{min}$ after annealing at 150°C for 2 h are shown. After annealing, the diffracted line from (002) plane of α' phase, $\alpha'(002)$, which had been observed in an as-deposited state, splits into two diffracted lines. One corresponds to $\alpha''(004)$ and/or $\alpha'(002)$ with satisfying stoichiometric N content of $\alpha''\text{-Fe}_{16}\text{N}_2$ (11 at. %). The other corresponds to $\alpha(002)$ of slightly deformed $\alpha\text{-Fe}$. For the film prepared under N_2 flow ratio of 16%, diffracted intensity from $\alpha(002)$ becomes zero

FIG. 2. Electron diffraction pattern of $\alpha''\text{-Fe}_{16}\text{N}_2$ film annealed at 150°C for 2 h. M and α correspond to reflections of MgO and α -phase, respectively. Indexes with underline correspond to superlattice reflections of α'' phase.

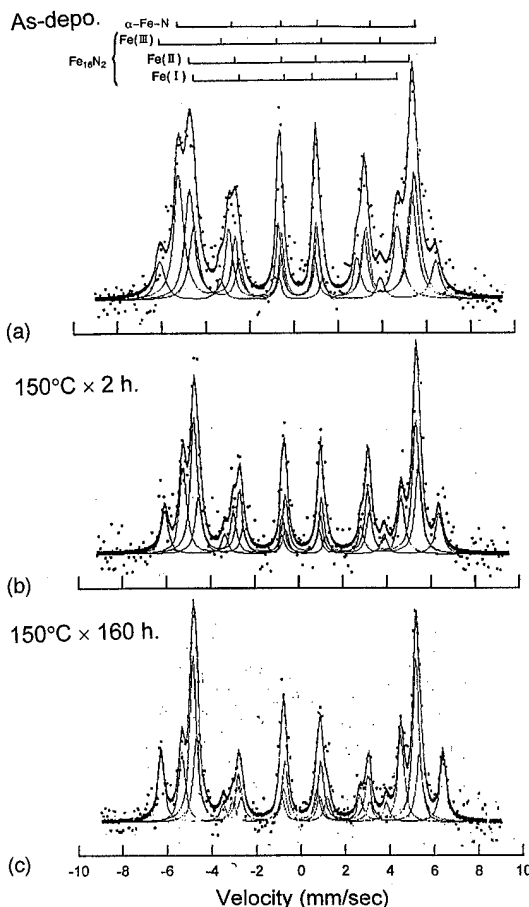

FIG. 3. Mössbauer spectra of $(\alpha''+\alpha')\text{-Fe}_{16}\text{N}_2$ film (non-Cu coated) measured at RT (a) as-deposited, (b) annealed at 150°C for 2 h, and (c) annealed at 150°C for 160 h, respectively.

and only diffracted line of $\alpha''(004)$ was found (nearly α'' single phase). Furthermore, simultaneously at around 33° of 2θ , $\alpha''(002)$ which is the unique diffracted line from the α'' phase, comes to be clearly observed. This means that the ordering of N atoms was promoted by annealing while retaining the bct structure and the α'' phase with stoichiometric N content was synthesized.

To confirm the phase formation of $\alpha''\text{-Fe}_{16}\text{N}_2$ in real films in more detail, x-ray diffraction was made for the lattice plane including a axis of the bct unit cell. The unique diffractions from (103), (105), (112), (114), and (213) planes of the α'' phase, including the a axis for $(\alpha''+\alpha')\text{-Fe}_{16}\text{N}_2$ film, are clearly observed.¹⁻³ Therefore, the existence of the α'' phase is reconfirmed by these clear unique diffracted lines. The values of the lattice constants a and c of the present films coincided with reported values of the $\alpha''\text{-Fe}_{16}\text{N}_2$ precipitates in bulk powder.¹⁶

Figure 2 shows the electron diffraction pattern of the α'' -phase film annealed at 150°C for 2 h. The superlattice reflections from (200), (002), (101), (110), (301), and (103) of α'' phase are clearly observed, accompanied with the extra diffractions from $\alpha\text{-Fe}$. By using these superlattice reflections, determined values of lattice constants a and c of the α'' phase are almost equal to the results obtained by XRD analysis.

Figure 3 shows the changes of Mössbauer spectra of the

TABLE I. Time dependence of the Mössbauer parameters for the Fe_{16}N_2 films.

Site	Hi (kOe)	I.S. (mm/s)	e.q.Q. (mm/s)	W_{wid} (kOe)	Area (%)

Fe(III)	400	0.1431	-0.06	2.50	17.4
α -Fe-N (Annealed at 150 °C for 160 h)	336	0.0250	-0.002	2.50	17.9

Fe_{16}N_2 film with stoichiometric N content by annealing. The fitted Mössbauer parameters are listed in Table I. The spectrum in each film can be fitted into four hyperfine field interactions of H_i . One is H_i of the α -Fe-N phase (I.S. value differs slightly from that of pure α -Fe) and the others are that of Fe(I), Fe(II), and Fe(III) of three different Fe sites for the $(\alpha''+\alpha')$ - Fe_{16}N_2 phase. The site population of the $(\alpha''+\alpha')$ - Fe_{16}N_2 phase after annealing 160 h is about 4:7.6:3.2, which is close to the ideal ratio of 4:8:4 determined uniquely from the structure factor of α'' - Fe_{16}N_2 . Half width of the peaks become narrower with increasing annealing time. This result corresponds to the promotion of N site ordering in nitrogen martensite caused by annealing. The volume fraction of the $(\alpha''+\alpha')$ - Fe_{16}N_2 phase is estimated about 82% after annealing for 160 h.

It is concluded that even in present sputtered films, α' phase with completely the same structure as precipitates in bulk powder is formed.

2. α' , α' - $\text{Fe}_{16}(\text{N-H})_2$ films

Here, turning around the previous experiments concerning Fe nitrided films and powders with giant magnetic mo-

FIG. 4. X-ray diffraction patterns for the Fe-H films fabricated under various H_2 flow ratio.

ment, we can find experimental conditions in common that in most cases samples were synthesized by using NH_3 gas.^{7,8,11} Therefore, it is interesting to know how the nitriding process of Fe atoms was changed by using reactive sputtering under N_2+H_2 mixtured atmosphere. In this section, in order to clarify the role of H atoms for the nitriding process, H_2 gas was introduced into the $\text{Ar}+\text{N}_2$ atmosphere during film fabrication. The effect of doping of hydrogen on the phase formation of Fe nitrided phase is discussed.

Figure 4 shows the changes of x-ray diffraction patterns for Fe-H films prepared under $\text{Ar}+\text{H}_2$ atmosphere with different H_2 flow ratio. Only the diffracted lines from (002) plane of α' phase were detected at around 2θ of $74-78^\circ$. These diffracted lines shift to low angle of 2θ with increasing H_2 flow ratio. Namely, lattice spacing of (002) plane of α' increases with increasing H_2 flow ratio. Axial ratio, c/a , determined by using the Schultz reflection method, takes constant value about 1.01 up to 60% H_2 flow ratio and increases slightly up to 1.02 around 95% H_2 flow ratio. It is noted here that even in the films prepared under $\text{Ar}+\text{H}_2$ atmosphere, bcc structure with slight deformation from α -Fe was realized in the same way as films sputtered under $\text{Ar}+\text{N}_2$ atmosphere.

Figure 5 shows x-ray diffraction patterns for films (as-deposited) fabricated under $\text{Ar}+\text{N}_2$ atmosphere (Ar :1.8 ccm, N_2 :0.2 ccm) and under the $\text{Ar}+\text{N}_2+\text{H}_2$ atmosphere (Ar :1.8 ccm, N_2 :0.2 ccm; H_2 :8.0 ccm), respectively. Here, the same deposition rate was adapted between two different sputtering atmospheres, since the degree of nitriding of Fe strongly depends on the deposition rate. As seen in Fig. 5, for the films prepared under $\text{Ar}+\text{N}_2$ atmosphere without H_2 gas, the diffracted line from α' phase was detected. On the other hand, contrary to the film prepared under $\text{Ar}+\text{N}_2$ atmosphere with H_2 , the diffracted lines from γ' - Fe_4N and α' - Fe_{16}N_2 phase were clearly observed. This fact means that the adding of H_2 gas into $\text{Ar}+\text{N}_2$ atmosphere during sputtering makes nitriding of Fe atoms accelerate.

3. α' , α' -($\text{Fe}_{100-x}\text{Co}_x$) $_{16}\text{N}_2$ films

In the Fe-Co binary alloy system, it is known that (1) bcc structure is stably formed up to the composition of 75 at. % Co at RT, that (2) lattice constant a of Fe-Co alloys shows almost constant value up to Co content of 30 at. %, and

FIG. 5. X-ray diffraction patterns for sputtered films fabricated under $\text{Ar}+\text{N}_2$ atmosphere (Ar :1.8 ccm, N_2 :0.2 ccm) and $\text{Ar}+\text{N}_2+\text{H}_2$ atmosphere (Ar : 1.8 ccm, N_2 :0.2 ccm, H_2 :8.0 ccm), respectively.

FIG. 6. X-ray diffraction patterns for $\text{Fe}_{90}\text{Co}_{10}\text{-N}$ films (as-deposited state) fabricated under different N_2 flow ratio.

and that (3) the magnetic moment of Fe-Co alloys increases with increasing Co content and takes a maximum of $2.46 \mu_B$ at 30 at. % Co.¹⁷ By considering the above physical properties of Fe-Co alloys, it seems to be able to synthesize $\alpha''\text{-(Fe}_{100-x}\text{Co}_x)_{16}\text{N}_2$ in the same way as Fe-N films. From the physical standing point of view, it is interesting to know that (1) change of σ_s as a function of Co content for $\alpha''\text{-(Fe}_{100-x}\text{Co}_x)_{16}\text{N}_2$, and that (2) the giant magnetic moment proposed up to now for $\alpha''\text{-Fe}_{16}\text{N}_2$ phase is induced or not for $\alpha''\text{-(Fe}_{100-x}\text{Co}_x)_{16}\text{N}_2$ films.

In this section, the possibility of the formation of α' and $\alpha''\text{-(Fe}_{100-x}\text{Co}_x)_{16}\text{N}_2$ ($X=0\text{--}30$) phase with stoichiometric N content is discussed as a function of Co content.

As an example, in Fig. 6, the changes of the x-ray diffraction patterns as a function of N_2 flow ratio, $F_{\text{N}_2}/F_{\text{total}}$, for $(\text{Fe}_{90}\text{Co}_{10})\text{-N}$ films in an as-deposited state was shown. The diffraction line from (002) of $\alpha'\text{-(Fe}_{90}\text{Co}_{10})\text{-N}$ phase [$\alpha'_{\text{Fe-Co}}(002)$] with various N content up to stoichiometric N content of 11 at. % were clearly detected. On the other hand, in the case of $(\text{Fe}_{70}\text{Co}_{30})\text{-N}$ films, the intensity of diffraction line from $\alpha'_{\text{Fe-Co}}(002)$ becomes to be weak with increasing $F_{\text{N}_2}/F_{\text{total}}$, and the diffracted line from $\alpha_{\text{Fe-Co}}(002)$ gradually appears. Namely, $\alpha'\text{-(Fe}_{70}\text{Co}_{30})\text{-N}$ phase was formed up to 4 at. %, however $\alpha'\text{-(Fe}_{70}\text{Co}_{30})\text{-N}$ with stoichiometric N content of 11 at. % was not synthesized.

In Fig. 7, temperature dependencies of σ_s for the $\alpha'\text{-(Fe}_{100-x}\text{Co}_x)\text{-N}$ ($X=10\text{--}30$) films fabricated under $F_{\text{N}_2}/F_{\text{total}}$ of 6% are shown. These films consist of nearly α' single phase with various N content of 4–8 at. %. In Fig. 7, the temperature dependence of σ_s for $(\alpha''+\alpha')\text{-Fe}_{16}\text{N}_2$ film (11 at. % N) annealed after 150 °C for 2 h is also shown for comparison.

As reported in previous articles,^{2–4} in the case of the $(\alpha''+\alpha')\text{-Fe}_{16}\text{N}_2$ film, the value of σ_s decreases monotonously with increasing measuring temperature. Around 200 °C a sudden discontinuous decrease of σ_s was observed. From XRD analysis this discontinuous change of σ_s corresponds to the phase decomposition from $(\alpha''+\alpha')\text{-Fe}_{16}\text{N}_2$ phase to $\alpha\text{-Fe}$ and $\gamma'\text{-Fe}_4\text{N}$ phases. While in the case of $\alpha'\text{-(Fe}_{100-x}\text{Co}_x)\text{-N}$ ($X=10\text{--}30$) films, similar discontinuous

FIG. 7. Temperature dependence of σ_s for the $\alpha'\text{-(Fe}_{100-x}\text{Co}_x)\text{-N}$ ($X=10\text{--}30$) films fabricated under N_2 flow ratio of 6%.

changes of σ_s against measuring temperature were also observed. These discontinuous changes also correspond to the phase change from $\alpha'\text{-(Fe}_{100-x}\text{Co}_x)\text{-N}$ to $\alpha\text{-(Fe}_{100-x}\text{Co}_x) + \gamma'\text{-(Fe}_{100-x}\text{Co}_x)_4\text{N}$. However, it should be noted here that the temperature where the phase decomposition takes place decreases with increasing Co content from 200 °C for $(\alpha''+\alpha')\text{-Fe-N}$ martensite to 100 °C for $\alpha'\text{-(Fe}_{80}\text{Co}_{20})\text{-N}$ film and RT for $(\text{Fe}_{70}\text{Co}_{30})\text{-N}$ film, respectively. This means that the phase decomposition temperature of $\alpha'\text{-(Fe}_{100-x}\text{Co}_x)\text{-N}$ ($X=0\text{--}30$) phase strongly depends on Co content.

In Fig. 8, the phase decomposition temperature, $T_{\text{p.d.}}$, from $\alpha'\text{-(Fe}_{100-x}\text{Co}_x)\text{-N}$ martensite phase to $\alpha\text{-(Fe}_{100-x}\text{Co}_x)$ and $\gamma'\text{-(Fe}_{100-x}\text{Co}_x)_4\text{N}$ was replotted against Co content. For the films prepared under the same $F_{\text{N}_2}/F_{\text{total}}$, $T_{\text{p.d.}}$ decreases with increasing Co content. While for the films with the same Co content, $T_{\text{p.d.}}$ also decreases with increasing $F_{\text{N}_2}/F_{\text{total}}$. In other words, the phase decomposition temperature, $T_{\text{p.d.}}$ strongly depends not only on Co content but also on N content in $\alpha'\text{-(FeCo)-N}$ phase. Therefore it is concluded that stable formation of $\alpha''\text{-(Fe}_{100-x}\text{Co}_x)_{16}\text{N}_2$ ($X=10\text{--}30$) phase through the ordering process of N atoms by postannealing is fairly difficult in the Fe-Co alloy system.

B. Magnetic moment

1. Dependence of magnetic moment on unit-cell volume

Figure 9 shows the changes of σ_s against unit-cell volume of the α' phase with various N contents in an as-deposited state. In Fig. 9, $1/8$ of the unit-cell volume of the

FIG. 8. The changes of phase decomposition temperature, $T_{p.d.}$, ($\alpha'-(\text{Fe}_{100-x}\text{Co}_x)-\text{N} \rightarrow \alpha-(\text{Fe}_{100-x}\text{Co}_x) + \gamma'-(\text{Fe}_{100-x}\text{Co}_x)_4\text{N}$) against Co content.

$\alpha''\text{-Fe}_{16}\text{N}_2$ phase is indicated. Filled marks correspond to the annealed ($\alpha'' + \alpha'$)- Fe_{16}N_2 films with stoichiometric N content. In the same figure, σ_s for the Cu-coated films are also shown.

For the films consisting of α' single phase (in an as-deposited state), the values of σ_s increase slightly with the increment of the unit-cell volume. At the unit-cell volume of about 25.5 \AA^3 (α' phase with 11 at. % N), σ_s showed 228 emu/g on average (Cu coated) and this value is about 4% higher compared to that of bulk $\alpha\text{-Fe}$.

In the case of annealed ($\alpha'' + \alpha'$)- Fe_{16}N_2 films (Cu coated), the value of σ_s shows 232 emu/g on average, and are about 2% larger than that of each as-deposited film, while the unit-cell volume of the α'' phase is always constant and coincided with that of the bulk α'' phase. The unit-cell volume of the $\alpha'\text{-Fe-N}$ phase with 11 at. % N is equal to that of the $\alpha''\text{-Fe}_{16}\text{N}_2$ phase within the accuracy of this experiment. Therefore the change of σ_s by annealing in nitrogen-martensite with 11 at. % N content cannot be discussed as a function of the change of unit-cell volume of a bct structure caused by the phase transition from α' to α'' phase.

2. Dependence of magnetic moment on N site ordering

To evaluate the degree of N site ordering in the bct structure of nitrogen-martensite, two factors should be taken into account. One is the change of the integrated intensity of the $\alpha''(002)$ line which is the unique superlattice diffraction from the α'' phase. Another is the integrated intensity ratio of $\alpha''(004) + \alpha'(002)$ to $\alpha''(002)$, R_1 , namely

$$R_1 \equiv [I_{\alpha''(004)} + I_{\alpha'(002)}] / I_{\alpha''(002)} \quad (1)$$

The calculated value of R_1 is about 8 for the ideal structure of the α'' phase.

Figure 10 shows the change of XRD profiles against annealing time for the film with stoichiometric N content of

FIG. 9. Changes of σ_s as a function of unit-cell volume: (1) α' phase with various nitrogen contents in an as-deposited state, and (2) annealed ($\alpha'' + \alpha'$)- Fe_{16}N_2 films with and without Cu coating. H and L correspond to high (240 $\text{\AA}/\text{min}$) and low (33 $\text{\AA}/\text{min}$) deposition rates, respectively.

the $\alpha'' + \alpha'$ phase (11 at. %). From these profiles, any diffraction lines from α and γ' phases are not observed. After annealing for 2 h, $\alpha''(002)$ comes to be observed clearly. With increasing annealing time, the integrated intensity of $\alpha''(002)$ increases. On the other hand, the experimentally determined value of R_1 changes from 50 to about 15 with increasing annealing time.

Therefore, from these experimental results (1) the increase of the integrated intensity of $\alpha''(002)$ and (2) the change of R_1 approaching to the ideal value of 8, the increment of degree of N site ordering in nitrogen-martensite, which directly corresponds to the increase of the volume fraction of the α'' phase in the films, is strongly promoted by annealing.

In Fig. 11, the changes of σ_s in ($\alpha'' + \alpha'$)- Fe_{16}N_2 films by isothermal annealing at 150°C are shown against the integrated intensity ratio R_1 . The increment of σ_s does not show any drastic changes against R_1 even though R_1 approached to the value of 8. Only σ_s increases slightly about 3% by annealing. However, with further increasing annealing time, in all cases, from these experimental facts, it was found that the degree of N site ordering in nitrogen-martensite does not much affect the increment of σ_s . The expected values of σ_s at $R_1 = 8$ (perfect ordered state in $\alpha''\text{-Fe}_{16}\text{N}_2$) estimated by the simple extrapolation using these data points of σ_s against R_1 are no more than 240 emu/g, which is definitely smaller than the giant magnetic moment of 2.9 T ($\approx 315 \text{ emu/g}$).

On the other hand, as seen in the fitted Mössbauer parameter shown in Table I, for the present films, the average value of H_i was about 325 kOe, which is nearly equal to that of H_i of $\alpha\text{-Fe}$. Therefore, the value of σ_s in ($\alpha'' + \alpha'$)- Fe_{16}N_2 film of about 232 emu/g determined by vibrating-sample magnetometer (VSM) was consistent with the result of

FIG. 10. The change of x-ray diffraction patterns as a function of annealing time for the film with stoichiometric N content of the α'' phase (11 at. % N).

Mössbauer spectrum analysis. Based on the fitted Mössbauer parameters, the volume fraction of $(\alpha'' + \alpha')$ - Fe_{16}N_2 in annealed films is estimated to be 82%. Using these experimental values, the value of σ_s in the $(\alpha'' + \alpha')$ - Fe_{16}N_2 phase, $\sigma_{\text{Fe}_{16}\text{N}_2}$, is estimated by the following equation:

$$232^{\text{exp}} = \sigma_{\text{Fe}_{16}\text{N}_2} \times 0.82 + \sigma_{\alpha\text{-Fe}} \times 0.18, \quad (2)$$

where $\sigma_{\alpha\text{-Fe}}$ is 218 emu/g. The obtained value of $\sigma_{\text{Fe}_{16}\text{N}_2}$ is 235 emu/g.

Considering this calculated result and the result of the dependence of σ_s on R_1 , we can conclude that the value of saturation magnetization of the α'' phase (perfect order state) should not be exceeded more than 240 emu/g, which agrees well with the result of the recent theoretical band calculation.¹⁸

3. Dependence of magnetic moment on Co content

Figure 12 shows the change of σ_s for α' -(Fe-Co) $_{16}\text{N}_2$ films in an as-deposited state (non-Cu coated) against Co content. In Fig. 12 the change of σ_s for Fe-Co binary alloy film against Co content was also shown for comparison. As mentioned in the previous section of this article, for the films with Co content up to 10 at. %, α' -(Fe-Co)-N with stoichiometric N content of 11 at. % was synthesized. However, for the film with Co content of 20 at. %, α' phase up to about

FIG. 11. The changes of σ_s against R_1 for the Fe_{16}N_2 films.

FIG. 12. The changes of σ_s against Co content for α' -(Fe-Co) $_{16}\text{N}_2$ films.

7 at. % N was synthesized. However, α' with stoichiometric N content could not be synthesized. Therefore, in Fig. 12, as a reference, the value of σ_s for α' - $\text{Fe}_{80}\text{Co}_{20}$ -N film with N content of 7 at. % was shown.

For the Fe-Co binary alloy films prepared in pure Ar plasma (non-Cu coated), σ_s increases from about 215 to 240 emu/g with increasing Co content. This dependence of σ_s on Co content coincides with the well-known Slater-Pauling curve. While the values of σ_s for α' -($\text{Fe}_{100-x}\text{Co}_x$)-N with stoichiometric N content of 11 at. %, films show 220 emu/g for $X=0$ and 228 emu/g for $X=10$. For α' -($\text{Fe}_{80}\text{Co}_{20}$)-N film with 7 at. % N, σ_s shows 232 emu/g. This dependence of σ_s on Co content in α' -($\text{Fe}_{100-x}\text{Co}_x$)-N with stoichiometric N content of 11 at. % is completely the same as that of Fe-Co binary alloy films. In the increment of σ_s only about 3% is observed.

Judging from the dependence of σ_s for α' -(Fe-Co)-N films with stoichiometric N content of 11 at. % on Co content, we can conclude again that the value of intrinsic saturation magnetization of α' - Fe_{16}N_2 phase should be no more than 240 emu/g.

Electronic and magnetic structure of iron nitride, Fe₁₆N₂ (invited)

Akimasa Sakuma

Magnetic and Electronic Materials Research Laboratory, Hitachi Metals, Ltd., Mikajiri 5200, Kumagaya 360, Saitama, Japan

The result of spin-polarized band calculation for Fe₁₆N₂ is presented. The most distant Fe atoms from N is found to have the largest magnetic moment. The major role of the N atom is to expand the Fe lattice, leading to the enhancement of the magnetic moments. Quantitatively speaking, the calculated moment of Fe₁₆N₂ is about 2.4 μ_B which is much smaller than the measured value reported. It is also shown that the correction with the orbital magnetic moment and the generalized gradient approximation (GGA) cannot account for this discrepancy. From the point of view of the many body effects, a possibility of the giant moment is also discussed. An important feature of this model is a generation of hopping sites with the N atoms, which likely promotes a ferromagnetic coupling of Fe atoms keeping their large spin-polarization in the atomic limit. © 1996 American Institute of Physics. [S0021-8979(96)10108-4]

I. INTRODUCTION

Until the early 1970s, the relationship between ferromagnetism and metal-nonmetal bonding of iron nitrides was the main subject of research for both theory and experiment.¹⁻⁹ In 1972, Kim and Takahashi¹⁰ reported a giant magnetic moment in the Fe-N film. Since then, much work has been carried out on the magnetism in the compounds of the transition metals with the elements such as N, C, and B. The interest in such nitrogenated metals was further accelerated through the discovery of new hard magnetic materials, Sm₂Fe₁₇N_x (Ref. 11) and NdFe₁₁TiN.¹² The work by Kim and Takahashi showed that their Fe-N film consisted of both Fe and Fe₁₆N₂.¹³ Much effort has been made to reproduce their result, but there is difficulty because of the uncertainty in estimating accurate moments in multiphase materials. Therefore, some groups tried to prepare the single phase Fe₁₆N₂ with several techniques. In 1990, Komuro *et al.*¹⁴ were first able to grow a single crystal Fe₁₆N₂ film onto InGaAs epitaxially by molecular beam epitaxy (MBE) technique. They obtained B_S of the Fe₁₆N₂ to be 2.8–3.0 T. Concurrently, Nakajima *et al.*¹⁵ also succeeded in fabricating Fe₁₆N₂ films by ion implantation and measured the “average” magnetic moment of Fe atom to be about 2.5 μ_B . After all these pioneer works, many experimental studies were initiated to examine if the giant magnetic moment was really present or not.¹⁶⁻¹⁹ Up till now, the data reported by several workers varies from one to another. Among them the moment measured by Takahashi *et al.*¹⁷ was not high at all, but close to that of α -Fe. According to the recent data by Sugita *et al.*,^{20,21} the average magnetic moment per Fe atom reaches about 3.5 μ_B at -268 C with help from site ordering of the N atoms in the Fe lattice. The data is apparently projected from one of the other iron nitrides. Therefore, it is very important to theoretically predict such an extremely large moment in Fe₁₆N₂ and to discuss how the magnetism of Fe₁₆N₂ is related to that of both N-martensite and other iron nitride compounds.

The band calculation for γ' -Fe₄N was carried out by Wei Zhou *et al.*,²² and the present author²³ based on the local spin density functional theory. Also, the calculations for the Fe₁₆N₂ were performed by many workers.²⁴⁻³³ These results

indicate that the theoretical “average” moment per Fe atom is about 2.4–2.5 μ_B , except for one by Lai *et al.*,³² which will be discussed later. Thus, the result based on the band calculation is at a variance with the experimentally obtained value of Fe₁₆N₂. In this paper, the results of the band calculation of Fe₁₆N₂ is presented. Further, the magnetism of the Fe₁₆N₂ is discussed on the basis not only of the improved band theory, but also of the many body scheme for a highly correlated system.

II. DENSITY OF STATES

First, discussion of the calculated density of states (DOS) of Fe-N in conjunction with the experimental results of the x-ray photoemission spectroscopy (XPS) data⁹ is made. The DOS of Fe₄N in paramagnetic (spinless) state is shown in Fig. 1, where the dashed line is for fcc-Fe which leads to Fe₄N with inclusion of the N atom at the body center. The structure around -0.6 to -0.4 Ry in the DOS of

FIG. 1. Comparison of the density of states of paramagnetic Fe₄N (solid line), fcc-Fe (dashed line) and the photoemission data by Ertl *et al.* (Ref. 9). The zero on the energy scale corresponds to the Fermi energy, E_F .

FIG. 2. Total density of states of Fe_4N (up) and Fe_{16}N_2 (down). The energy is measured with respect to the E_F .

Fe_4N is attributed to the N atom, which belongs mainly to the 2p states. Roughly speaking, both the energy position and the intensity of the N 2p state coincide with the observed XPS peak around -0.5 Ry which is enhanced with N concentration. This feature is also agreeable with DOS within accuracy. It should be noted that the peaked feature of DOS of Fe_4N at the Fermi level, E_F , is a consequence of the paramagnetic state, which means that the system is stabilized with a help of spin polarization.

Calculated results of the spin-polarized DOS of Fe_4N and Fe_{16}N_2 are shown in Fig. 2. The key features are common for all compounds as follows. The isolated structures located around -1.2 Ry are mainly due to 2s states of N. The main structures around the Fermi energy, E_F , are almost composed of 3d, 4s, and 4p states of Fe. The E_F 's are pinned at around the dip position in down spin electron density of states, which makes these states stable with the help of spin polarization. As mentioned previously, the N 2p bands are found at about -0.6 Ry to -0.4 Ry below the 3d bands, which can be observed in XPS. Furthermore, Ertl's experimental results⁹ that no change in the 3d bands occurs during nitration can be understood by noting that the features of 3d bands are nearly the same for these compounds.

III. MAGNETIC MOMENT

As previously reported,²³ the feature of local densities of states of each Fe in Fe_4N and Fe_{16}N_2 is considerably different depending on the site. It should be marked that the most distant Fe atoms from the N atom, FeI for Fe_4N and FeIII for Fe_{16}N_2 , have the large 3d hole in the down spin states just above the E_F , while the up spin states of the sites are almost occupied. Actually, the local magnetic moments of these sites are the largest as shown in Table I which also gives several other calculated results for comparison. The electron numbers of these sites are found to be smaller about 0.3 to 0.6 than that of other sites. So it can be considered that the large moments of these sites are attributed mainly to the shortage of down spin electrons rather than the receipt of the up spin electrons. The variations of these charge distribution on each Fe site can be regarded as an effect of the N atom. Thus, the present result that the moments of FeI and FeII in Fe_{16}N_2 are nearly the same is due to the fact that the distances from the N atom are nearly the same for these sites.

Based on the above results, it should be noted that the most distant Fe atoms from the N atom have the largest magnetic moments for Fe_4N and Fe_{16}N_2 . This is related to the bonding nature between N atom and surrounding Fe atoms. Actually, the variance of the moments on each Fe site has been shown to be brought about by the redistribution of the down spin electrons due to the electronic interference by the interstitial N atoms. This event reflects the relative arrangement of the Fe atoms against the N atoms in these compounds. According to Kanamori,³⁴ the elements such as B, C, and N enhance the magnetic moments of the next nearest neighboring Fe atoms. That is, the 3d levels, especially the down spin state of the nearest neighbor (NN) Fe atoms to the N atoms ($\text{Fe}_{1\text{st}}$ in Fig. 3) are lowered through the hybridization with a part of the N 2p state located around the E_F and in turn the 3d down spin state of the next NN Fe atoms ($\text{Fe}_{2\text{nd}}$ in Fig. 3) are raised conversely. As a result, the electrons mainly of the down spin states transfer from the next NN Fe atoms to the NN Fe atoms (see Fig. 3). This electronic bonding feature is strongly responsible for the variation of the local magnetic moments of each Fe site in the iron nitride system. Actually, the Mössbauer and neutron diffraction measurements for Fe_4N support the above picture

FIG. 3. The local DOS of Fe atoms are changed from solid lines to dashed lines with the inclusion of the N atom and, then the electrons mainly of the down spin states transfer from the $\text{Fe}_{2\text{nd}}$ to the $\text{Fe}_{1\text{st}}$. As a result, the local magnetic moment of $\text{Fe}_{2\text{nd}}$ is raised while one of $\text{Fe}_{1\text{st}}$ lowers.

and the magnetic structure can be quantitatively reproduced by the present calculation.

As to the average moments, the present result indicates that the lattice expansion due to N atoms plays a major role in the enhancement of the magnetic moments. In Fig. 4, we give the average magnetic moment of each compound as a function of N concentration. Our calculated result for bcc Fe is also shown in the figure. Though the quantitative agreement with the experiments cannot be reached for Fe_{16}N_2 , the dependence of the moments on the N concentration can be proved qualitatively. The behavior that the lower concentration of N atoms leads to larger magnetic moment may be understood by the following argument. An interstitial N atom expands the interatomic distance not only of the nearest neighboring Fe atoms but also of the next nearest neighboring and more distant Fe atoms for avoiding the lattice distortion. This certainly enhances the moments of the system even

FIG. 4. N concentration dependence of the average magnetic moments of iron nitrides. The open circles indicate the calculated results, and the closed squares and the bar are from the measured values (from the data by Ref. 4 for Fe_3N , Ref. 6 for Fe_4N and Refs. 14–20 for Fe_{16}N_2).

TABLE II. Spin and orbital magnetic moments (μ_B) of Fe_{16}N_2 and bcc-Fe.

	Fe II	2.26	0.066
	Fe III	2.82	0.082
bcc-Fe		2.23	0.062

though the concentration of N atom is low. Additionally, as mentioned previously, the N atoms play a role as hopping sites for the electrons, which in turn prevents the exchange splitting concurrently. (Note that this may be inseparable from the charge redistribution which gives the variance of the local magnetic moments.) Eventually, it comes to the conclusion that a lower concentration of N atom is preferable for a larger magnetic moment.

IV. INSPECTION FOR THE MAGNETISM OF Fe_{16}N_2

For Fe_{16}N_2 , the calculated magnetic moment is much smaller than the experimental value. A recent result by Sugita *et al.*²¹ of Fe_{16}N_2 amounts to $3.5 \mu_B$ at -268°C . Thus, the magnetic aspect of Fe_{16}N_2 seems to be quite outstanding in the series of iron nitrides. In this section, we discuss the magnetism of the Fe_{16}N_2 .

In Table II, we present the orbital moments of Fe_{16}N_2 calculated by introducing the spin-orbit interaction in the linear muffin-tin orbital (LMTO) Hamiltonian. The result for bcc Fe is also shown for comparison. Though the orbital moment of Fe_{16}N_2 is slightly larger than that of bcc Fe, it is still smaller, as compared to the case for usual transition metal systems. It is found that the orbital moment to the total cannot account for the discrepancy between theory and experiments. Actually, the g value of this film has been measured to be almost the same as one of bcc Fe.^{35,36}

Further we tried a nonlocal correction to the local density approximation with use of generalized gradient approximation (GGA)³⁷ and obtained an increase of magnetic moment as much as about $0.1 \mu_B$ per Fe atom. Thus, the nonlocal correction is also a minor contribution to the total magnetic moment.

Here let us turn to the foundation of the magnetism, apart from the band theory. The degree of spin polarization in solid is generally dominated mainly by a Coulomb repulsion acting selectively on antiparallel spins drawing near each other especially at around the nuclei. The Coulomb energy consumption for the parallel spins is much less because they are forbidden to draw near each other by the Pauli principle. The energy difference between the parallel and antiparallel spins leads to an exchange energy.

This mechanism can be connected to the Hund's rule in the atomic limit. According to this rule we expect $4 \mu_B$ for an isolated Fe atom. Here, we are led to the question; is there any scenario to give a situation that Fe atoms form solid with keeping their magnetic moment close to $4 \mu_B$ and with having ferromagnetic ordering? In the Hubbard model, an increase of the intra-atomic Coulomb interaction (U) comparing to the hopping integral (t) promotes a spin polarization

FIG. 5. Schematic representation of the electronic configuration in the d orbitals of Fe atom in the crystalline electric field (CEF) of bcc symmetry. (a) Fully spin-polarized case due to the Hund coupling, which can hardly make a ferromagnetic coupling with neighboring Fe atoms because of the Pauli principle. (b) Partially polarized case which allows ferromagnetic coupling with neighboring Fe atoms through electron hopping between $d\gamma$ orbitals.

in the three-dimensional metallic system. The basic concept of Lai *et al.*³² lies in this viewpoint. They postulated that the nitrogen atoms induce U on the Fe atoms.

Here, we try to focus on the other possible role of the nitrogen atom other than the enhancement of the U parameter. Consider a situation where the overlap of the Fe atomic wave functions is small enough in the bcc lattice. In this case, the d orbitals on each Fe atom split into three-fold degenerate $d\epsilon$ orbitals and twofold degenerate $d\gamma$ orbitals by a crystalline electric field (CEF). If six electrons belong to the d orbitals, the electronic configuration is expected to be given as shown in Fig. 5(a). When Fe atoms draw closely to each other, they are to be coupled mainly through an electron hopping between $d\gamma$ orbitals since they extend toward each other, while the $d\epsilon$ orbitals are relatively localized. However, if every Fe atom keeps its electronic configuration as Fig. 5(a), the Pauli principle prevents hopping of electrons of $d\gamma$ orbitals and thus interferes to form solid. One way to realize the interatomic coupling is, contradicting to the Hund coupling, a rearrangement of the electronic configuration as shown in Fig. 5(b) such that a part of electron transfer from up spin state to down spin state in order to make a vacant orbital in the $d\gamma$ orbitals. The atomic energy difference between the electronic configurations of Figs. 5(a) and 5(b) is approximately given by $\Delta E = E(b) - E(a) = 3K + U - V - \Delta$ where K is the exchange energy between different orbital, and U and V are direct Coulomb energy within same orbital and different orbital, respectively, Δ is the energy difference between $d\gamma$ and $d\epsilon$ orbitals. If these values are chosen as $U=5$ eV, $V=3$ eV, $K=1$ eV and $\Delta=1$ eV, one obtains $\Delta E=4$ eV. The value is comparable or lower than the cohesive energy per atom which is brought about mainly by the propagation of $d\gamma$ electrons. Thus, the electronic configuration in Fig. 5(b) is more stable with the electron hopping through vacant $d\gamma$ orbitals. The decrease of magnetic moment from $4\mu_B$ in pure iron can be ascribed mainly to this process. Other

FIG. 6. Model presenting a mechanism for fully polarized ferromagnetic metal. With inclusion of the N atom in the Fe lattice, slight hole is created in one of the $d\gamma$ orbitals split further by the tetragonal distortion. This promotes a hopping of $d\gamma$ electrons and gives rise to the interatomic coupling, without destroying the Hund coupling acting within each Fe atom.

possible ways to realize the coupling is to introduce, in the Fe lattice, an additional hopping site having vacant orbitals. This may effectively provide a slight hole in the Fe lattice. If Hund coupling is sufficiently large, down spin electrons which belongs to $d\epsilon$ orbitals have a chance to transfer to a vacant orbital. However, once a lattice distortion is induced with inclusion of the additional atom such as tetragonal distortion, one of the $d\epsilon$ orbitals becomes more localized with its energy lowered (Fig. 6). In this case, it is feasible that the hole is created in the $d\gamma$ orbital shifted to a higher energy level with lattice distortion. When the $d\gamma$ electrons move in the solid, interatomic coupling can be realized without destroying the Hund's rule, and the ferromagnetic ordering can be expected. This is because the itinerant $d\gamma$ electrons align the direction of the total spin of each Fe site through lattice hopping accompanied with Hund coupling with $d\epsilon$ electrons. Under the condition where the hole concentration is not so large and that a sufficient strength of the Hund coupling is held, the Fe atoms can be expected to form ferromagnetic metal, with their moments close to $4\mu_B$.

Previous experimental result (electron diffraction measurement⁸) and the band calculations^{22,23} for well-established Fe_4N predicted that the N atoms act as an acceptor in the Fe lattice. This supports that the N atoms contribute to the creation of holes in the relevant system. The feature can also be easily anticipated from the fact that the oxygen atoms in the transition metal oxides behave as anion. As to Fe_4N , however, CEF on each Fe atom makes $d\epsilon$ orbitals higher energy than the $d\gamma$ orbitals. In this case, the Hund rule in the atomic limit may be easily destroyed since the highly degenerate $d\epsilon$ orbitals are delocalized and act as a main conduction band. Thus, the present model in which both the Hund coupling and the electron hopping can coexist requires the condition that the inclusion of the nitrogen atoms does not destroy the body center lattice and the long range ordering of the atomic structure. This could provide an interpretation that there exists an optimum N concentration for giving a giant moment, while it does not necessarily require $[\text{N}]/[\text{Fe}]=1/8$ to give the largest moment. In addition, the condition of the long range ordering may be consistent with the experimental results that a giant moment requires a site ordering of the N atom in the Fe lattice.²¹

Whereas the essence of the result by Lai *et al.* is an enhancement of the electron correlation energy U , the key feature of the present model is an effect of N atoms as a hopping site in the Fe lattice. This is closely related to the mechanism invented for the metallic ferromagnetism of $\text{La}_{1-x}\text{M}_x\text{MnO}_3$ ($M = \text{Ca, Sr, etc.}$). For $x = 0$, this system is an antiferromagnetic insulator and exhibits phase transition to ferromagnetic metal with a partial substitution of La by M element ($x > 0$). The magnetic moment on Mn site is about $4 \mu_B$. The metallic ferromagnetism of this system has been interpreted in terms of the double-exchange interaction^{38,39} connected to the Hund coupling.^{38,39} Recently, this has been intensively studied with the Kondo lattice model^{40,41} in order to understand both the magnetism and the giant magnetoresistance. The distinctive feature of the present model is an introduction of the interstitial site instead of the substitution for the hole creation. Therefore, the Kondo lattice model with a ferromagnetic coupling can also be applied to the present system.

According to our recent study⁴² for the Kondo lattice model, the Curie temperature (T_c) is lower than $0.1 D/k_B$ (K) even for large JS/D limit where D , S , and J are the half width of the conduction band, localized spin and Hund coupling parameter, respectively. The conduction band width we are concerned about may be a few eV. From this, the T_c must be a same level or lower comparing with the iron. This supports the experimental measurement of the T_c of Fe_{16}N_2 by Sugita *et al.*²¹

The most serious problem of this model is whether the $d\epsilon$ orbitals can maintain the localized aspect like an atomic state even in the solid. As shown by most studies, band calculations always give negative results to this question. However, once the electron correlation energy or the Hund coupling energy exceeds the energy gain due to a kinetics of the electrons in the lattice, the electrons prefer to be localized on each site and to form atomic state. From the view point of many body theory, this situation is expressed in terms of the band narrowing or the mass enhancement of the electrons. Even with a recent band calculation taking into account the correlation energy through density functional theory, the intra-atomic Coulomb energy is generally underestimated. Therefore, there is always a possibility that the localized picture of the electrons in solids cannot be accounted for properly by the band calculation, as many theoreticians have experienced in most transition metal oxides. The trial by Lai *et al.* is one of the ways to attack this problem, though the other approaches can also improve the band calculation procedure independently. In an actual system of Fe_{16}N_2 , there may exist a possibility that the effect of tetragonal distortion makes the overlap of $d\epsilon$ orbitals further small with a splitting into twofold and nondegenerate orbitals (see Fig. 6).

Note that the present analysis does not immediately give a direct interpretation to the giant magnetic moment, because in the present model we took into account only the side view of the system which may not be accounted properly in the local density functional approximation. What we should insist here is that there may exist a case where the electron correlation plays a crucial role in the magnetism even in a metallic system. A compromise between the band model and

the many body effects in such a critical region is desired.

V. SUMMARY

We have summarized the result of spin-polarized band calculation for Fe_{16}N_2 . Also given is the result of Fe_4N for comparison. As to the local magnetic moments, the most distant Fe atoms from N have the largest magnetic moment. The major role of the N atom is to expand the Fe lattice to enhance the magnetic moments. It should be noted, however, that the N atoms help a hopping of the electrons and then prevent the exchange splitting. As a consequence, the lower concentration of the N atom gives a larger magnetic moment. Quantitatively, the calculated moment of Fe_{16}N_2 is far below the experimental data by Sugita *et al.* which is quite outstanding in the series of other iron nitrides. A possibility of the giant moment has been discussed in view point of the many body effects. Essence is a generation of hopping sites with N atoms, which may promote a ferromagnetic coupling of Fe atoms keeping its large spin polarization in the atomic limit. The model requires the intra-atomic Coulomb interaction such as Hund coupling on each Fe atom, combined with the interatomic propagation of $d\gamma$ electrons with a help of the hole doping in the lattice. Our main emphasis is that the band theory is never a panacea for the magnetism as well as for the cuprate superconductivity. Experimentally, more refined analysis for the crystal structure such as local arrangement of Fe and N atoms and the magnetic data such as neutron diffraction are desired.

The average magnetic moment per Fe atom for a single-phase, single-crystal $\text{Fe}_{16}\text{N}_2(001)$ film epitaxially grown on a GaAs(001) substrate by molecular beam epitaxy has been confirmed to be $3.5\mu_B$ at room temperature by using a vibrating sample magnetometer (VSM) and Rutherford backscattering. The value was in good agreement with that obtained by using a VSM and by measuring the film thickness ($3.3\mu_B$ per Fe atom). The saturation magnetization $4\pi M_s$ has been found to increase with decreasing temperature, obeying $T^{3/2}$ law at lower temperatures. The slope was steeper than that of a pure Fe film, suggesting a lower exchange constant for Fe_{16}N_2 . The g factor for Fe_{16}N_2 has been accurately measured to be 2.17 by using ferromagnetic resonance with changing frequencies of 35.5–115 GHz, which is not unusual compared with the g factor of 2.16 for pure Fe. The resistivity for Fe_{16}N_2 has been measured to be around $30\mu\Omega\text{ cm}$ at room temperature compared with $10\mu\Omega\text{ cm}$ for pure Fe and decreases linearly with decreasing temperature. The behavior was that for normal metal and nothing unusual was seen. The anomalous Hall resistivity for Fe_{16}N_2 was $4\times 10^{-7}\text{ V cm/A}$, which is about three times as large as that for pure Fe. The relationship between the giant magnetic moment and the anomalous Hall resistivity has not been clarified yet. © 1996 American Institute of Physics. [S0021-8979(96)25508-2]

I. INTRODUCTION

Since the pioneering work on high saturation magnetization of Fe–N films including Fe_{16}N_2 crystallites was reported by Kim and Takahashi,¹ much attention has been paid to the magnetic properties of Fe–N, especially Fe_{16}N_2 films. The Fe_{16}N_2 compound itself was discovered earlier by Jack² as precipitates formed in Fe–N powders by low temperature annealing.

Quite recently, Komuro *et al.*^{3,4} and Sugita *et al.*^{5,6} have grown single-phase, single-crystal $\text{Fe}_{16}\text{N}_2(001)$ films of 300–900 Å thickness epitaxially on $\text{In}_{0.2}\text{Ga}_{0.8}\text{As}(001)$ substrates using molecular beam epitaxy (MBE). They found that the saturation magnetization $4\pi M_s$ of Fe_{16}N_2 is around 29 kG at room temperature and around 32 kG at 5 K, respectively. Those values are equivalent to the average magnetic moment of 3.2 and $3.5\mu_B$ per Fe atom at room temperature and 5 K, respectively. These are truly giant magnetic moments, much greater than the Slater–Pauling curves⁷ and the average magnetic moments for Fe_{16}N_2 calculated based on the conventional band theory of several authors.^{8–15}

Also several experiments to prepare Fe_{16}N_2 films or powders and foils have been carried out using methods other than MBE, such as sputtering,^{16–22} ion implantation,^{23–25} and ammonia nitrification.^{26–31} In most cases, the samples were not single-phase Fe_{16}N_2 , but mixtures of several phases such as Fe, Fe_{16}N_2 , Fe–N martensite, Fe_4N , etc. Therefore, there can be some significant ambiguities in estimated values of $4\pi M_s$ for Fe_{16}N_2 and other data such as hyperfine fields.

In this study, the average magnetic moment per Fe atom for a single-phase Fe_{16}N_2 film has been measured by using a vibrating sample magnetometer (VSM) and Rutherford back-

scattering (RBS). Here, the number of Fe atoms included in the film has been obtained without measuring the film thickness. Also the temperature dependence of $4\pi M_s$, the g factor, and the temperature dependence of the resistivity and the anomalous Hall resistivity for Fe_{16}N_2 have been investigated in detail.

II. EXPERIMENT

A. Sample preparation

Fe_{16}N_2 films were prepared in an atmosphere of mixed gas of N_2 and NH_3 by using a MBE apparatus equipped with electron-beam evaporation sources. $\text{In}_{0.2}\text{Ga}_{0.8}\text{As}$ and GaAs(001) single-crystal wafers were used as substrates. Details of the deposition conditions were described in a previous paper.⁶

FIG. 1. X-ray diffraction (XRD) and reflection high energy electron diffraction (RHEED) patterns for a sample of Fe_{16}N_2 .

FIG. 2. Transmission electron diffraction spots for a cross section of a sample cleaved along the (110) plane of a GaAs substrate.

Samples were confirmed to be single-phase, single-crystal $\text{Fe}_{16}\text{N}_2(001)$ films by the x-ray diffraction and reflection high energy electron diffraction (RHEED) patterns as shown in Fig. 1 and also by the transmission electron diffraction as shown in Fig. 2. The photo was taken for a cross-sectional sample cleaved along the (110) substrate plane and thinned down to around 2000 Å by polishing and ion milling. The electron beam spot was around 100 Å in diameter and the acceleration voltage was 200 kV. All diffraction spots were identified as figures of planes of Fe_{16}N_2 and spots from other phases were not seen. The ratio of the lattice parameter of the c axis to that of the a axis is determined to be 1.1 from the (004) and (220) spots, which agrees well with the previously reported value.² Pure Fe films were also prepared on $\text{In}_{0.2}\text{Ga}_{0.8}\text{As}$ and $\text{GaAs}(001)$ substrates in a vacuum of 5×10^{-7} Torr for comparison with Fe_{16}N_2 films and reference for measurements.

B. Characterization

1. Rutherford backscattering

The amounts of Fe atoms included in films were measured with Rutherford backscattering (RBS). A sample was bombarded by He ions with 8° inclination and reflected ions were detected with a counter as shown schematically in Fig. 3. The channel of the analyzer was 2.3 keV. The energy of

FIG. 3. Schematic view of a RBS experiment.

FIG. 4. Schematic RBS spectra.

the incident He ions was 2.3 MeV and the diameter of the He ion beam was 1 mm.

RBS spectra are schematically shown in Fig. 4. The spectra are composed of two parts, one from the substrate atoms, Ga and As, and the other from the film atoms, Fe. From the intensity $H(E_1)$ and the area of the signal from the film, the total number of Fe atoms can be obtained based on the established method.³²

2. Ferromagnetic resonance

Ferromagnetic resonance (FMR) measurements were carried out on Fe_{16}N_2 films along with pure Fe films using microwave sources with 35.5, 49.5, 90.0, and 115 GHz. Magnetic fields up to 60 kOe were applied parallel and perpendicular to the film plane using a superconducting magnet. The samples were 2-mm-diam circular plates defined by chemical etching. Sample temperature was kept at 77 K. From FMR data, the g factors of Fe_{16}N_2 and Fe films were obtained.

3. Measurement of magnetic moment

Magnetic moments of samples were measured by using a superconducting quantum interference device (SQUID) magnetometer at temperatures from 10 to 300 K and also by using a VSM at temperatures from 77 to 700 K.

4. Resistivity and Hall resistivity measurements

Resistivity and Hall resistivity measurements were made on Fe_{16}N_2 films along with pure Fe films at temperatures from 10 to 300 K. Samples used for resistivity measurements

FIG. 5. RBS spectra measured for a Fe film grown on a GaAs substrate.

FIG. 6. RBS spectra measured for a Fe_{16}N_2 film grown on GaAs.

were $1\text{ mm} \times 4\text{ mm}$ with four terminals made of Au. Samples used for Hall resistivity measurements were $3\text{ mm} \times 3\text{ mm}$. Hall resistivities were measured by van der Pauw's method.³³ That is, the current was supplied through terminals located at a pair of opposite corners with magnetic field applied perpendicular to the film and the Hall voltage generated between the terminals located at another pair of opposite corners was measured.

III. RESULTS AND DISCUSSION

A. Magnetic moment per Fe atom

Typical RBS spectra measured for Fe and Fe_{16}N_2 films are shown in Figs. 5 and 6. Those samples are $6\text{ mm } \phi$, $860\text{-}\text{\AA}$ -thick Fe and $8\text{ mm } \phi$, $340\text{-}\text{\AA}$ -thick Fe_{16}N_2 films grown on GaAs(001) substrates. Simulated lines based on previously known data for Ga, As, and Fe are in good agreement with measured data in both cases. Here, the edge energies for As and Ga atoms (around 1800 keV) in Fig. 5 are slightly different from those (around 1900 keV) in Fig. 6. The reason for the difference is due to the difference in film thickness between Fe ($\sim 860\text{ \AA}$) in Fig. 5 and Fe_{16}N_2 (340 \AA) in Fig. 6.

From the intensities and areas of the signals from Fe atoms, the densities (atoms cm^{-2}) of Fe atoms of the films are obtained as shown in Table I. Using the data of magnetic moments measured with a VSM for those samples, the average magnetic moments per Fe atom for Fe and Fe_{16}N_2 are obtained to be $2.16\mu_B$ and $3.53\mu_B$ at room temperature, respectively. The value obtained for Fe is very close to that

FIG. 7. Temperature dependence of the saturation magnetization $4\pi M_s$ for a Fe_{16}N_2 film along with a Fe film.

obtained by using the volume of the sample and also to the bulk value.⁷ This confirms the accuracy of the data by this method without measuring the film thickness. For Fe_{16}N_2 , the obtained value is a little higher than that obtained by using the volume of the sample, but the difference is small and this data confirms the giant magnetic moment of Fe_{16}N_2 .

It should be noticed here that for Fe and Fe_{16}N_2 films grown on $\text{In}_{0.2}\text{Ga}_{0.8}\text{As}(001)$ substrates, it is almost impossible to get the accurate values by this method. This is because the signals from Fe and In atoms appear at almost the same positions in RBS spectra, therefore the amount of Fe atoms is hardly obtained accurately.

B. Temperature dependence of $4\pi M_s$

The saturation magnetization $4\pi M_s$ has been measured using a SQUID, changing temperature from 10 to 300 K. The samples used for the measurements were 8-mm-diam circular plates accurately defined by using photolithography and chemical etching. Film thicknesses were measured with a needle contact feeler gauge.

Figure 7 shows the temperature dependence of $4\pi M_s$ for a Fe_{16}N_2 film along with that for a pure Fe film. In Fig. 7 $4\pi M_s$ is plotted as a function of $T^{3/2}$. In both cases, $4\pi M_s$ is linearly decreased with increasing temperature at lower temperatures, obeying the $T^{3/2}$ law expressed as³⁴

$$4\pi M_s(T) = 4\pi M_s(0)(1 - CT^{3/2}). \quad (1)$$

Here $4\pi M_s(T)$ and $4\pi M_s(0)$ are the values at a temperature of T and 0 K, respectively. By extrapolating the line to 0 K,

TABLE I. Average magnetic moment for a Fe_{16}N_2 film along with that for a Fe film.

Sample	He ion energy E_0 (MeV)	Atomic density t (atoms/ cm^2)	Sample shape	Magnetic moment (emu)	Magnetic moment per Fe atom (RBS)	Magnetic moment per Fe atom (thickness and XRD)
Fe/GaAs	2.3	7.17×10^{17}	$6\text{ mm } \phi$ 860 \AA	0.00405	$2.16\mu_B$	$2.14\mu_B$
$\text{Fe}_{16}\text{N}_2/\text{GaAs}$	2.3	2.42×10^{17}	$8\text{ mm } \phi$ 340 \AA	0.00400	$3.53\mu_B$	$3.28\mu_B$

TABLE II. Experimental data on the temperature dependence of $4\pi M_s$ for a Fe_{16}N_2 film along with those for a Fe film.

	Fe_{16}N_2	Fe
$4\pi M_s(0)$ (kG)	32.3	21.8
M_B (μ_B)	3.5	2.2
C ($\times 10^{-6}$ kG/K $^{3/2}$)	18	5.5
D (meV \AA^2)	70	220
D/T_C	0.08	0.2

$4\pi M_s(0)$ are obtained to be 32.3 and 21.8 kG for Fe_{16}N_2 and Fe, respectively, as shown in Table II. These values of $4\pi M_s$ are equivalent to the average magnetic moments per Fe atom of $3.5\mu_B$ and $2.2\mu_B$ at 0 K for Fe_{16}N_2 and Fe, respectively.

The slope of Eq. (1), $C(\text{kG/K}^{3/2})$ are 18 and 5.5×10^{-6} for Fe_{16}N_2 and Fe, respectively. C is expressed by³⁵

$$C = 2.612[g\mu_B/4\pi M_s(0)](k_B/4\pi D)^{3/2}. \quad (2)$$

Here g is the g factor, k_B is the Boltzmann constant, and D is the exchange interaction constant between magnetic moments of atoms. The g factors are 2.17 and 2.16 for Fe_{16}N_2 and Fe, respectively, as described in Sec. III C. Using those values, D (meV \AA^2) is obtained for Fe_{16}N_2 to be around 70, which is much smaller than the value for 220 for Fe, as shown in Table II. Even taking into consideration the lower Curie temperature T_C for Fe_{16}N_2 (around 810 K),⁵ the exchange constant is lower, because D/T_C for Fe_{16}N_2 is 0.08, while D/T_C for Fe is $0.2(T_C:1040 \text{ K})$.

In Fig. 8, $4\pi M_s(T)/4\pi M_s(0)$ is shown as a function of T/T_C for Fe_{16}N_2 and Fe. It is clear that the decrease of $4\pi M_s$ is much steeper for Fe_{16}N_2 than for Fe. The mechanism for this is not clear.

C. The g factor

The g factor for Fe_{16}N_2 was reported to be around 2.0,³⁶ but the measurement using FMR was not so accurate. This is because the frequency used in the previous work was fixed at 35.5 GHz and the applied field was 10 kOe at its highest and was not sufficient to saturate the magnetization perpendicular to the film plane.

FIG. 8. $4\pi M_s(T)/4\pi M_s(0)$ vs T/T_C for a Fe_{16}N_2 film along with that for a Fe film.

FIG. 9. FMR spectra for a Fe_{16}N_2 film measured at 49.50 GHz with magnetic field applied in the [110] direction of the film plane.

In this experiment, the frequency is changed from 35.5 to 115 GHz. The maximum applied field is 60 kOe. Typical FMR data at 49.5 GHz for a Fe_{16}N_2 film of 2 mm diam are shown in Figs. 9 and 10. Figure 9 shows the obtained data when the field is applied in the [110] direction of the film plane. There is some drift in absorption between increasing field and decreasing field processes, but the resonance field does not shift at all. Figure 10 shows the data for the case where the field is applied perpendicular to the film plane. In both cases, the magnetic field is calibrated using the FMR field for DPPH (α, α -diphenyl- β -picrylhydrazyl) with g of 2.0 as a standard.

In Fig. 11, the resonance field-frequency diagrams are shown for the three cases. The fields are applied in the [100] and [110] directions of the film plane, and applied in the

FIG. 10. FMR spectra for a Fe_{16}N_2 film measured at 49.50 GHz with magnetic field applied in the [001] direction perpendicular to the film plane.

FIG. 11. The relationship between the resonance frequency and the resonance field measured and calculated for the three cases with magnetic field applied in the [100], [110], and [001] axes. The dotted points are measured ones and the solid lines are calculated ones.

[001] perpendicular to the film plane. As previously reported³⁶ an Fe_{16}N_2 (001) film exhibits large uniaxial perpendicular anisotropy with easy axis parallel to the [001] and small anisotropy with easy axes of [100] and [101] in the film plane. The resonance equations for the above three cases as shown in Fig. 11 are expressed as follows:³⁴

$$[001] \quad \omega/\gamma = H_r + H_{k\perp} - 4\pi M_s, \quad (3)$$

$$[100] \quad (\omega/\gamma)^2 = (H_r + H_k)(H_r - H_{k\perp} + 4\pi M_s), \quad (4)$$

$$[110] \quad (\omega/\gamma)^2 = (H_r - H_k)(H_r - H_{k\perp} + 4\pi M_s - 1/2 H_k). \quad (5)$$

Here $\omega (= 2\pi f)$ is the resonance frequency; γ , the gyro-magnetic ratio; H_r , the resonance field; $H_{k\perp}$, the uniaxial anisotropy field, and H_k , the in-plane anisotropy field. From the data of Fig. 11, the g factor for Fe_{16}N_2 is obtained with least deviation using Eqs. (3)–(5). The value is 2.17.

FIG. 12. Temperature dependence of the resistivity ρ for a Fe_{16}N_2 film along with a Fe film.

FIG. 13. Hall resistivity ρ_H as a function of magnetic field applied perpendicular to the films plane for an Fe_{16}N_2 film along with a Fe film.

In those experiments, H_r is higher than 6 kOe for the case of the in-plane field FMR, which is high enough to saturate the magnetization. Also in the case of perpendicular field FMR, H_r is higher than 40 kOe, which is high enough to saturate the magnetization. Therefore FMR data were taken under the condition that Eqs. (3)–(5) are valid. Consequently the g factor of 2.17 is likely to be accurate. This is supported by the measurement of the g factor for a Fe film. The value obtained by using the same method is 2.16, which agrees well with previously reported data. Details of the FMR data will be reported elsewhere.

The g factor of 2.17 for Fe_{16}N_2 is not unusual at all due to its giant and unusual magnetic moment, but this cannot be contradictory.

D. Temperature dependence of resistivity and anomalous Hall resistivity

The temperature dependence of resistivity ρ for a Fe_{16}N_2 film is shown along with that for a Fe film in Fig. 12. ρ at room temperature is around $30 \mu\Omega \text{ cm}$, a little higher than the $10 \mu\Omega \text{ cm}$ for Fe. ρ is almost linearly decreased with decreasing temperature. The behavior is that for normal metal and nothing unusual is seen.

The Hall resistivity ρ_H versus applied field at room temperature for Fe_{16}N_2 is shown along with that for pure Fe in Fig. 13. ρ_H is increased linearly with increasing field and further is almost saturated. From those data, the saturated anomalous Hall resistivity $\rho_{AS} (= R_A 4\pi M_s)$ is obtained based on the following:

FIG. 14. Temperature dependence of the saturated anomalous Hall resistivity ρ_{AS} for an Fe_{16}N_2 film along with a Fe film.

FIG. 15. Temperature dependence of the anomalous Hall constant R_A for a Fe_{16}N_2 film along with a Fe film.

$$\rho_H = R_N H + R_A 4\pi M = \rho_N + \rho_A. \quad (6)$$

Here R_N and R_A are normal and anomalous Hall constants, respectively, and ρ_N and ρ_A are normal and anomalous Hall resistivities, respectively. ρ_{AS} for Fe_{16}N_2 is 4×10^{-7} V cm/A at room temperature compared with ρ_{AS} of 1.5×10^{-7} V cm/A for pure Fe. It is to be noted here that ρ_{AS} for Fe_{16}N_2 is about three times as large as that for Fe. The temperature dependencies of ρ_{AS} and R_A for Fe_{16}N_2 are shown along with those for Fe in Figs. 14 and 15, respectively. In both cases, ρ_{AS} and R_A are decreased with decreasing temperature. In the whole temperature range, ρ_{AS} and R_A for Fe_{16}N_2 are larger than those for Fe. The reason for those behaviors in ρ_{AS} and R_A and the relationship between anomalous Hall resistivity and the giant magnetic moment are not so clear.

IV. CONCLUSIONS

The average magnetic moment per Fe atom for a single-phase, single-crystal Fe_{16}N_2 film epitaxially grown by MBE has been confirmed to be $3.5\mu_B$ at room temperature with VSM and a Rutherford backscattering technique. The value was in good agreement with that of $3.3\mu_B$ obtained with VSM and measuring the film thickness.

The temperature dependence of the saturation magnetization $4\pi M_s$ for Fe_{16}N_2 has been found to obey the $T^{3/2}$ law at lower temperatures. The slope was much steeper than that for pure Fe, which suggested lower exchange coupling between magnetic moments of Fe atoms in Fe_{16}N_2 .

The g factor for Fe_{16}N_2 has been measured by FMR changing the frequency from 35.5 to 115 GHz and applying the magnetic field up to 60 kOe. The obtained value was 2.17, which was very close to the g factor of 2.16 for pure Fe.

The resistivity for a Fe_{16}N_2 film has been measured at temperatures from 10 to 300 K. The resistivity was around $30 \mu\Omega \text{ cm}$ at room temperature and decreased linearly with decreasing temperature. The behavior was that for normal metal and nothing unusual was seen. The saturated anomalous Hall resistivity has been found to be 4×10^{-7} V cm/A, which was about three times as large as that of pure Fe.

Thus the giant magnetic moment for Fe_{16}N_2 has been reconfirmed. Further, magnetic and electrical properties for Fe_{16}N_2 have been investigated in detail, which will be useful

to clarify the origin of the giant magnetic moment in future.

Mössbauer-effect study of face-centered-cubic-like Fe on Cu(001) (invited) (abstract)

W. Keune, A. Schatz, R. D. Ellerbrock, A. Fuest, K. Wilmers, and R. A. Brand
Laboratory of Applied Physics, University of Duisburg, D-47048 Duisburg, Germany

More than 30 years ago, Weiss¹ has postulated the existence of two different magnetic fcc-Fe states [high-spin (HS)/high atomic volume or low-spin (LS)/low atomic volume] in order to explain the Invar effect in fcc-Fe alloys. Such metastable states may be stabilized by epitaxial growth of ultrathin Fe films on Cu(001) under suitable conditions which depend on film thickness and growth temperature. *In situ* conversion-electron Mössbauer spectroscopy, combined with low-energy electron diffraction, reflection high-energy electron diffraction, and Auger electron spectroscopy, on ~ 3 - and ~ 7 -ML-thick ^{57}Fe films grown in ultrahigh vacuum at 300 K reveals a thickness-dependent transition from a HS ferromagnetic (FM) state with an anisotropically expanded fcc (fct-like) structure ($c/a > 1$) to a LS antiferromagnetic (AFM) isotropic fcc state. In contrast, the stability of the HS fct-like phase is extended to at least 7 ML in films grown at low T (90 K) and annealed to 300 K. The HS-FM phase in 7 ML films is rather stable against annealing up to 500 K; annealing at 570 K leads to a HS-LS transformation which is correlated with abrupt surface segregation of Cu. By placing 2-ML-thick isotopically enriched ^{57}Fe -probe layers into a 300 K grown natural Fe film of 7 ML total thickness we could obtain a magnetic depth profile along the film-normal direction: while the LS-AFM state (with $T_N \sim 70$ K) was found at the film center and a paramagnetic Fe-Cu alloy at the Fe/Cu interface, Fe surface atoms were observed to be in a HS-FM state with a noncubic atomic environment. Only today can we begin to understand the complex behavior of fcc-Fe/Cu(001). © 1996 American Institute of Physics. [S0021-8979(96)47508-6]

Magnetic properties of fcc-Fe multilayer (invited) (abstract)

M. Matsui, M. Doi, A. Kida, and Y. Yamada

Department of Materials Science, Nagoya University, Nagoya 464-01, Japan

Recently, magnetic properties of fcc-Fe ultrathin films have been extensively investigated. The results, however, are complicated and inconsistent with one another. These are antiferromagnetism, ferromagnetism, different Fe magnetic moment for different atomic sites in film or a rearrangement of surface Fe atoms etc. In this article the recent results for fcc-Fe multilayers will be reported and discussed to obtain a unified picture for magnetism of fcc-Fe ultrathin films. Epitaxially grown multilayers of fcc-Fe with Cu or Cu-M (M=Au,Ni) spacer on Cu(001) and Cu(111) substrates were prepared by molecular beam epitaxy method. The Cu-M spacer was adopted to change the mean interatomic distance between Fe atoms at interfaces by changing the composition of M (=Au,Ni), where Au was used to increase the distance and Ni to decrease it. Fe layers on a pure Cu spacer were fcc and the magnetic moment was at most $2.0\mu_B$. Fe layers on a Cu-Au spacer, however, were fct with $c/a < 1$ and those on Cu-Ni with $c/a > 1$, where a is the in-plane lattice constant and c is the out of plane one. Then a mean magnetic moment of Fe atoms (μ) as a function of Fe atomic volume (V) was obtained. The moment μ continuously increases with increasing V by the so-called magnetovolume effect. The maximum μ value is $2.7\mu_B$ for about $\Delta V = 4\%$ (ΔV is a change of V from pure Cu volume). And $\mu = 0$ for $\Delta V = -2\%$. The Mössbauer effect and EXAFS were also measured. The measurements revealed that the samples for the $\Delta V \leq 0$ region contain two kinds of Fe (mixture state), high spin state with $2.0\mu_B$ and nonmagnetic low spin state. Thus it is concluded that the high to low spin state transition is the first kind as theoretically suggested by Moruzzi *et al.* We also performed band calculations for fcc-Fe/Cu multilayers changing V . Next, the reason for the mixture state is discussed. It is found that a well defined smooth Cu substrate surface promotes a rearrangement of surface Fe atoms due to the surface diffusion, preferring the low spin state and the rough surface obstructs the rearrangement and provides the fcc circumstance by surrounding Cu atoms, which results in the high spin state. Recent inconsistent results for fcc-Fe ultra thin films could be explained by the two spin state model, the surface Fe atomic rearrangement, and the magnetovolume effect. © 1996 American Institute of Physics. We report giant magnetoresistance in annealed NiFeCo (2 nm)/Ag (3.3 nm) multilayers. For all samples, post-deposition annealing was necessary for the observation of GMR analogous to the NiFe/Ag discontinuous multilayer system. The GMR ratio and field sensitivity varied widely as a function of annealing from temperatures between 300 and 400 °C. A high MR ratio of 6.3% and field sensitivity of 11.3%/(kA/m) (0.9%/Oe) were observed for a seven bilayer sample annealed to 350 °C. In general, NiFeCo/Ag multilayers produced greater MR responses and field sensitivities than comparably annealed NiFe/Ag multilayers. NiFeCo/Ag multilayers, however, display more hysteresis than NiFe/Ag multilayers and lack a zero-crossing saturation magnetostriction versus annealing temperature. Multilayer deposition in a magnetic field severely degrades MR performance since it prevents the magnetostatic antiparallel alignment between magnetic grains which occurs in the absence of an applied magnetic field following sample annealing. © 1996 American Institute of Physics. [S0021-8979(96)53708-2]

I. INTRODUCTION

To prove useful in magnetic recording applications, a magnetoresistive material must display an appreciable magnetoresistive response and sensitivity in small magnetic fields. One material which meets the above criteria in the NiFe/Ag discontinuous multilayer discovered by Hylton *et al.*¹ In this system, post-deposition annealing is required to obtain GMR.¹ A possible mechanism to explain the onset of GMR after annealing is the diffusion of Ag along the columnar grain boundaries. This diffusion effectively breaks up the NiFe layers into grains that interact magnetostatically.^{1,2} An antiparallel magnetostatic coupling in the absence of an external magnetic field produces a maximum resistance; the resistance then decreases as a magnetic field is applied and the magnetic moments of the grains become aligned.

In an attempt to exceed the magnetoresistive performance found in NiFe/Ag multilayers, we have synthesized multilayers of NiFeCo/Ag.³ The addition of cobalt to the magnetic layers should result in an enhanced spin-dependent scattering of bulk origin. NiFeCo/Cu multilayers have been found to have large MR ratios in small saturation fields.^{4,5} The Ni₆₆Fe₁₆Co₁₈ composition is worthy of consideration since it has zero-magnetostriction and zero-magneto-crystalline anisotropy in single-layered films and shows a large GMR when multilayered with Cu.⁴

Annealed samples which exhibited sizable magnetoresistive responses were subjected to magnetostriction measurements. The saturation magnetostriction λ_s is a critical soft magnetic property which must have a low and tightly con-

trolled value since it frequently induces an undesirable magnetoelastic anisotropy during head fabrication.⁶

II. EXPERIMENT

NiFeCo/Ag multilayer films were deposited onto 76-mm-diam Si wafers maintaining 150 nm of thermal surface oxide using dc magnetron sputtering from Ni₆₆Fe₁₆Co₁₈, Ag, and Ta targets. Sputtering occurred at a dynamic argon pressure of 0.93 Pa (7 mTorr) with a deposition rate of 0.5 nm/s for all materials. System base pressures prior to deposition were of the order of 10⁻⁶ Pa (10⁻⁸ Torr). When required, a magnetic field of 6.8 kA/m (85 Oe) was applied to the substrate to promote magnetic ordering within the film. The nominal multilayer structures were of the form: Si/SiO₂(150 nm)/Ta(4.5 nm)/Ag(1.6 nm)/NiFeCo(2 nm)/[Ag(3.3 nm)/NiFeCo(2 nm)]_{N-1}/Ag(1.6 nm)/Ta(11 nm), where *N* is the number of bilayers (*N*=5,7,9). Samples with equal numbers of bilayers were produced with and without a magnetic field present during film growth. Following deposition, the central regions of the wafers were diced into 38 mm×6.4 mm strips and annealed. Annealing was performed in a rapid annealing furnace for 5 min in a 5% H₂-Ar ambient at temperatures of 320, 350, 370, and 400 °C.

The magnetoresistive response of samples was measured at room temperature using a four-point in-line geometry with magnetic fields up to 8 kA/m (100 Oe). The measuring current was applied perpendicular to the in-plane magnetic field. Magnetostriction was likewise measured at room temperature by a high-precision optical tester employing an in-plane rotating magnetic field and laser-beam deflection technique.⁷

TABLE I. The magnetoresistive responses and saturation magnetostriction for five, seven, and nine bilayer NiFeCo(2 nm)/Ag(3.3 nm) multilayer samples subjected to 5-min anneals from 340 to 400 °C in a 5% H₂-Ar ambient environment are depicted. The samples were deposited in the absence of a magnetic field.

Bilayers	Anneal temp (°C)	$\Delta R/R_s$ (%)	$d(\Delta R/R_s)/dH$ [%/ (kA/m)]	λ_s ($\times 10^{-7}$)
5	320	2.8	6.2	10.4
5	350	3.1	3.6	10.4
5	370	3.2	3.0	9.6
5	400	2.4	1.0	5.0
7	320	1.9	5.0	11.5
7	350	6.3	11.3	10.1
7	370	6.5	4.8	6.0
7	400	3.4	1.3	4.4
9	320	1.2	1.3	11.3
9	350	3.9	10.1	12.1
9	370	6.0	5.5	10.5
9	400	3.7	2.5	4.4

III. RESULTS AND DISCUSSION

Similar to NiFe/Ag multilayers,^{1,3,8} NiFeCo/Ag multilayers require post-deposition annealing to obtain a GMR response. Data for five, seven, and nine bilayer annealed samples deposited without a magnetic field are listed in Table I. The GMR ratio and field sensitivity vary widely as a function of annealing temperature. The MR response, $\Delta R/R_s$, first increases then decreases as the annealing temperature is increased, regardless of the number of bilayers present in a sample. As Table I shows, a seven bilayer sample yielded the best MR performance with a $\Delta R/R_s = 6.5\%$ for an annealing temperature, T_{an} , of 370 °C. This was also the case for NiFe/Ag discontinuous multilayers where a seven bilayer sample showed $\Delta R/R_s \sim 5\%$ for $T_{an} = 370$ °C.⁸ The maximum sensitivity $d(\Delta R/R_s)/dH$ does not correlate with the maximum $\Delta R/R_s$ for five, seven, or nine bilayers. The best $d(\Delta R/R_s)/dH$ is 11.3%/ (kA/m) (0.9%/Oe) found in the seven bilayer sample annealed to 350 °C. This sample's MR response is only slightly reduced from the best overall MR response and is illustrated in Fig. 1. As a comparison, a NiFe/Ag multilayer with nominally identical preannealing magnetic and spacer layer thicknesses showed a 2.7% MR ratio and a 5%/ (kA/m) (0.4%/Oe) field sensitivity.⁸

The properties of NiFeCo/Ag multilayers are not, however, completely superior to those of NiFe/Ag multilayers. The MR transfer curves for NiFeCo/Ag multilayers tend to be more hysteretic than comparable transfer curves for NiFe/Ag multilayers. For example, the separation between peaks in Fig. 1 is ~ 1.1 kA/m (~ 14 Oe). This represents some of the smallest hysteresis present within the sample set listed in Table I. MR transfer curves for NiFe/Ag multilayers, on the other hand, have peak separations less than 0.3 kA/m (~ 4 Oe).⁹ The increased hysteresis present in NiFeCo/Ag multilayers is likely due to an increased coercivity associated with the addition of cobalt. In addition to larger hysteresis, NiFeCo/Ag multilayers yield less-desirable magnetostrictive behaviors. The saturation magnetostriction λ_s of NiFeCo/Ag

FIG. 1. Magnetoresistive response of a seven bilayer NiFeCo (2 nm)/Ag(3.3 nm) multilayer annealed for 5 min at 350 °C in a 5% H₂-Ar ambient environment. The maximum magnetic field sensitivity $d(\Delta R/R_s)/dH$ is 11.3%/ (kA/m) (0.9%/Oe).

multilayers does not have a zero-crossing analog like the zero crossing of the curves λ_s versus annealing temperature found systematically in NiFe/Ag.^{8,9} Instead, λ_s for NiFeCo/Ag multilayers remains positive for all annealing temperature between 320 and 400 °C. The saturation magnetostriction for NiFeCo/Ag multilayers does, however, decrease as the annealing temperature is increased yielding magnetostriction values of 10^{-6} or lower for materials displaying a large GMR and field sensitivity.

Films which mirrored the number of bilayers and annealing temperature listed in Table I but deposited in a magnetic field were also tested for magnetoresistive response. In all cases, the MR transfer curves revealed extremely poor responses. Among these, the highest $\Delta R/R_s$ value attained was 1.4%. Responses less than 1% were typical. The field sensitivities in all cases were low enough that they were not definable. The inability of these samples to show GMR after annealing is attributed to a magnetic anisotropy produced during deposition which retains sufficient strength during annealing to prevent antiparallel magnetostatic coupling between magnetic grains in the absence of an applied magnetic field.

IV. SUMMARY

In summary, we have observed giant magnetoresistance in annealed NiFeCo (2 nm)/Ag (3.3 nm) multilayers. The resulting MR responses and field sensitivities were highly dependent upon the annealing temperature. A high MR ratio of 6.3% and field sensitivity 11.3%/ (kA/m) (0.9%/Oe) were observed for a seven bilayer sample annealed to 350 °C. NiFeCo/Ag multilayers exhibit larger MR responses and field sensitivities than annealed NiFe/Ag multilayers, but with more hysteresis and higher saturation magnetostrictions. The application of a magnetic field during deposition led to a systematic and detrimental reduction in MR response.

Finite-size effect and its temperature dependence of giant magnetoresistance in magnetic granular materials

Jian-Qing Wang^{a)} and Gang Xiao

Physics Department, Brown University, Providence, Rhode Island 02912

In magnetic granular alloys such as Co-Ag, a large finite-size effect in giant magnetoresistance (GMR) has been observed as the sample thickness (t) varies. The value of GMR monotonically decreases and eventually vanishes as t approaches zero. The t range, over which the GMR value drops rapidly to zero, has been found to be weakly dependent on temperature. Our results are consistent with a picture that a strong spin-orbit interaction at surfaces is responsible for randomizing spins in different spin channels, thus reducing GMR. © 1996 American Institute of Physics. [S0021-8979(96)53808-9]

It has been observed that giant magnetoresistance (GMR) in magnetic granular materials depends critically on various dimensional constraints such as magnetic particle size and interparticle distance.¹⁻³ These dependencies reflect the dominance of the magnetic interface scatterings. Recently, a study⁴ on the finite-size effect of GMR has shown that GMR depends strongly on the sample thickness (t). Granular Co-Ag and Fe-Ag thin films, which both show GMR in bulk materials, do not exhibit GMR effect in the two-dimensional (2D) limit. Below a certain length scale which is on the order of the mean free path, GMR monotonically decreases from the bulk value toward zero as t approaches zero.

In heterogeneous magnetic systems, the mechanism responsible for GMR is the spin-dependent scattering of two spin channels. The spin preserving scattering is generally thought to be dominant in controlling the magnetotransport behavior. In magnetic multilayers, there has been a clear demonstration that the spin-flipping scattering influences GMR.⁵ Spin-flipping scattering reduces the GMR magnitude by mixing electrons in the two spin channels. There has been no strong evidence that spin-flipping scatterings substantially affect GMR in bulk granular materials. In thin films, however, the existence of surfaces may introduce spin-flipping scattering,⁶ and cause GMR to decrease. Our earlier study has indicated⁴ that the enhanced spin-orbit interaction at the surfaces causes spin randomization, and hence is responsible for the observed finite-size effect.

There are other interactions that cause spin flipping. One example is the electron-magnon interaction. Our earlier study was carried out at $T=4.2$ K, where electron-magnon interaction can be neglected. At higher temperatures, the strongly T -dependent electron-magnon interaction needs to be considered. It is the subject of the present work to investigate the temperature dependence of the finite-size effect of GMR in granular materials. We have found that although the value of GMR for a particular sample does depend on temperature, the thickness dependence of GMR is nearly independent of temperature. This finding further supports the picture that the surface induced spin-orbit interaction which is T independent is mainly responsible for the finite-size effect.

Our samples were fabricated using a high vacuum

magnetron-sputtering system with a base pressure better than 1×10^{-7} Torr during the deposition. To reduce random variation, each series of samples of varying thicknesses was deposited in a single run with a constant sputtering rate and onto a single 2×5 cm² glass substrate. A computer controlled stepping shutter was swept across the substrate in steps. The sample thickness at each step was precisely controlled by the duration of exposure time. The step-wedged samples were subsequently patterned into Hall bars by photolithography for magnetotransport measurements. All the samples used in this study were protected by a layer of photoresist immediately after deposition to avoid oxidation. They were not thermally annealed.

The thickness dependence of GMR is presented in Fig. 1 for Co₂₀Ag₈₀ granular films measured at $T=4.2$ K. To characterize GMR quantitatively, we use the net change in resistivity ($\Delta\rho$) from zero field to a high field ($H=8$ T). At $H=8$ T, the resistivity [$\rho(H)$] is nearly saturated. The commonly used magnetoresistance ratio, $\Delta\rho/\rho$, is not an appropriate parameter for investigating the finite-size effect, because it is also sensitive to other scatterings, such as disorder, of non-magnetic origin. We choose Co₂₀Ag₈₀, a GMR material whose bulk form has been studied extensively.^{2,3} The data in Fig. 1 consist of measurement on two series (denoted by solid dots and triangles) of thin films fabricated under identical

FIG. 2. Measured $\Delta\rho$ vs temperature T for samples of various thicknesses. The numbers by the curves in descending order indicate the sample thicknesses in the same order. Note that the curves of the two thick samples ($t=315$ and 203 nm) overlap with each other, indicating reaching the bulk limit.

tical conditions. The two sets of data are rather consistent between each other. The inset shows the quantity $\Delta\rho/\rho(0)$ in cycling magnetic field (± 8 T) for a bulk sample with a thickness of 315 nm. It is seen that $\rho(H)$ is almost saturated at 8 T and the bulk sample carries a GMR value of about 40% . At $T=4.2$ K, the zero field $\rho_{4.2\text{ K}}$ is about $27\text{ }\mu\Omega\text{ cm}$ for a bulk sample. The resistivity ratio $\rho_{4.2\text{ K}}/\rho_{300\text{ K}}$ is about 1.1 . As t reduces to 5 nm, $\rho_{4.2\text{ K}}$ increases about 40% due to the surface scatterings. Over the whole t range (5 – 320 nm) studied, the low- T spontaneous magnetization and the size of the magnetic particles remain constant within the experimental uncertainty.⁴

The variation of $\Delta\rho$ with t can be characterized by an initially slow decrease with t in thick samples and a rapid decrease in the thin-film region ($t < 50$ nm). In the 2D limit (t approaching zero), GMR can no longer be sustained. A phenomenological relation $\Delta\rho = \Delta\rho_b(1 - e^{-t/t_0})$, where $\Delta\rho_b$ is the bulk value of $\Delta\rho$, gives a reasonable description of the t dependence. The constant t_0 represents a characteristic length scale, that we call the decay length, of the finite-size effect. We believe that the origin of the finite-size effect observed is the enhanced spin-orbit interaction⁶ on the surfaces of a thin film. The strong spin-orbit coupling induces spin-flipping scatterings which tend to equalize the different electron mean free paths of the two spin channels. Qualitatively, the larger the surface effect, the longer the decay length t_0 .

In addition to the spin-orbit interaction, electron-magnon scattering is also detrimental to GMR, particularly at high T .⁷ The study of thermal effect on our samples may provide insight to the mechanism of the observed finite-size effect. For most of our samples we have measured $\Delta\rho$ as a function of T [$\Delta\rho(T)$] from 4.2 to 300 K. The results are presented in Fig. 2 for eight thicknesses. Note that the $\Delta\rho(T)$ curves for the two thick samples ($t=203$ and 315 nm) coincide with each other, due to the bulk nature of these samples. Figure 2 shows that $\Delta\rho(T)$ shares almost identical T dependence regardless of the film thickness.

In Fig. 3(a), we present $\Delta\rho$ as a function of t at various

FIG. 3. (a) Net resistivity change $\Delta\rho(T)$ vs t at various temperatures. Solid symbols represent measurement data for different sample thicknesses. The thin lines are guides to the eyes. The numbers in descending order give the temperatures for the data curves in the same order. (b) Decay length $t_0(T)$ vs temperature.

temperatures. By fitting the curves with $\Delta\rho(T) = \Delta\rho_b(T) \times [1 - e^{-t/t_0(T)}]$, we have obtained the decay length $t_0(T)$ in the T range of our measurement. The derived $t_0(T)$ is shown in Fig. 3(b). Over the temperature range studied, $t_0(T)$ is weakly dependent on T , increasing only 20% from 4.2 to 295 K. This result further affirms that the dominant mechanism behind the finite-size effect is the surface induced spin-orbit interaction, whose strength is independent of T . A finite T does slightly affect the finite-size effect by increasing $t_0(T)$ albeit by a small amount. There are a few possible causes. Thin films may develop a softening in magnetic structure at finite T , particularly on the surfaces. It is also possible that electron-magnon interaction may be slightly enhanced at the surfaces.

In conclusion, we have studied a finite-size effect of GMR with respect to the sample thickness and its temperature dependence. We found that GMR monotonically decrease with thickness reaching zero as t approaches zero within a decay length of 15 nm. We also found that this decay length is weakly dependent on temperature, which indicates that the main mechanism of finite-size effect is the surface induced spin-orbit interaction.

United Kingdom

We have investigated the thickness dependence of the giant magnetoresistance (GMR) observed in AgNiFe heterogeneous alloy films. The films were sputtered from a mosaic target at the system ambient temperature onto glass substrates. In order to maintain interfacial uniformity, and to control the spin-dependent transmission of electrons at the AgNiFe film interfaces, they were covered by 200-Å-thick NiFe under- and overlayers. The samples have total thicknesses in the range 400–3000 Å. The film resistivity, magnetoresistivity, and magnetization were measured in the temperature range 4–300 K and in fields of up to 1.1 T and the structure examined using both large- and small-angle x-ray diffraction. The results indicate that the observed thickness dependence of the GMR of the AgNiFe films is within the experimental error. It is postulated that this is due to coherent spin transmission of conduction electrons across the sandwich interfaces which does not degrade the GMR by mixing of the spin currents. © 1996 American Institute of Physics. [S0021-8979(96)53908-9]

I. INTRODUCTION

The recent discovery of the giant magnetoresistance (GMR) of magnetic multilayers¹ and heterogeneous alloy films² has led to much current worldwide interest in this technologically important effect. Heterogeneous alloys consist of a superparamagnetic nanocrystalline structure in which fine particles of a ferromagnetic material are embedded in a nonmagnetic matrix material. They are formed by the co-deposition of two immiscible metals, one of which is ferromagnetic in bulk. To promote phase segregation the film is either deposited at an elevated temperature or annealed after deposition. When the particles moments are randomly oriented the materials resistivity is higher than when they are aligned by the application of an external magnetic field. It is now generally accepted³ that GMR is due to spin-dependent scattering of electrons both within and at the interfaces of the ferromagnetic entities (either films or particles).

It has been found that the effect is a sensitive function of both the size of the ferromagnetic particles and the concentration of the ferromagnetic material in the alloy.⁴ The former effect has been postulated to be due to the existence of an optimum particle size, determined by the conduction electron mean free path⁵ (larger particle sizes result in a reduction of the GMR due to the decrease in particle surface to volume ratio), and the latter effect to the onset of percolation, which acts to couple the particles ferromagnetically.

In multilayers the current flow can be directed either parallel to the plane of the multilayer (CIP GMR) or with more difficulty perpendicular to it (CPP GMR). In CIP-GMR conduction electrons average the properties of the multilayer in the direction perpendicular to the multilayer plane on the length scale of their mean free path, however, it has recently been shown that this is not the case for CPP GMR.⁶ For this

geometry the key damping parameter in determining the GMR is the spin diffusion length l_{sf} . Analysis of CPP-GMR experiments⁷ indicates that l_{sf} is $\approx 10^3$ Å and is therefore very much longer than both the electron mean free path and the thicknesses of the nonmagnetic and ferromagnetic films comprising the multilayer. It is also predicted that when l_{sf} is shorter than the film thicknesses, the CPP GMR will decrease as $\exp(-t_N/2l_{sf})$, where t_N is the thickness of the nonmagnetic film.⁶ Such behavior has recently been reported for Co/Ag multilayers in which l_{sf} has been limited by the introduction of Mn impurities to increase spin-orbit scattering.⁸ As a typical granular structure contains magnetic particles of mean diameter ≈ 10 –40 Å which are separated by ≈ 10 –200 Å it is clear that l_{sf} will also be of critical importance in determining the GMR in these materials. Any mechanism, such as spin-dependent interfacial scattering or the jitterbug effect,⁹ which acts to mix the spin channels and therefore shorten the spin diffusion length, will therefore degrade the GMR.

GMR in heterogeneous alloys has previously been modeled by considering the self-averaging of the electric-field lines passing through the granular structure.¹⁰ This model predicts that the GMR is quadratic in H and depends strongly on the size of the ferromagnetic particles, the electron mean free paths, and the ratios of the spin-dependent to spin-independent scattering potentials of the particles and interfaces. A second model identifies both the spin-dependent scattering potential and density of states of the d band as being possible origins of the GMR.¹¹ This model also predicts a quadratic dependence of the GMR on applied field, providing spin-flip scattering is negligible and is supported by measurement of the magnetothermopower of Co–Ag granular alloys.¹² More recently the GMR has been consid-

ered within the framework of a modified effective exchange interaction model.¹³ This model treats the spin-dependent scattering as arising from an exchange interaction potential between the conduction electrons and magnetic scatterers.

In order to elucidate the effect of spin mixing we have investigated the thickness dependence of the resistivity and GMR. In principle the GMR in heterogeneous alloys should not be thickness dependent provided that the particle size distribution remains constant with thickness. However, this will not be the case if electrons scattered from the film interfaces lose their spin memory, i.e., they are spin flipped, thereby mixing the spin currents and decreasing the spin diffusion length. Such effects have recently been reported for CoAg,^{14,15} and FeAg,¹⁶ thin films and discussed in terms of the spin-flip scattering rate.¹⁵

II. EXPERIMENT

NiFe/Ag–Ni–Fe/NiFe films were rf sputtered onto glass microscope slides at the system ambient temperature. The base pressure was $<2 \times 10^{-7}$ Torr, the sputtering pressure was 8 mTorr of argon, and the sputtering power was 100 W for both the NiFe and the AgNiFe films. The targets used consisted of a 4 in. Ag (99.999%) disk onto which were placed Ni₈₁Fe₁₉ (99.97%) squares arranged in a mosaic pattern and a Ni₈₁Fe₁₉ (99.95%) 4 in. target. The film thickness was measured by interferometry and the composition determined using energy-dispersive x-ray analysis (EDAX). The Ag content of the films was fixed at 78 ± 5 at. %.

The resistivity and magnetoresistivity of the films were measured using a computer-controlled four-point dc method in a continuous-flow He cryostat over the temperature range 3.8–300 K in fields of up to 1.1 T. Magnetic measurements were made at 10 K using a PAR 155 vibrating sample magnetometer (VSM) fitted with an Oxford Instruments CF1200 continuous-flow He cryostat.

III. RESULTS

The magnetoresistance measured at 10 K is shown for five representative samples in Fig. 1. As can be seen from this figure the GMR decreases by a factor of ≈ 2 as the thickness of the AgNiFe film is decreased to 300 Å, however, this may be due to a number of factors other than a thickness dependence (e.g., changes in the film composition or particle size distribution or magnetization). Reduction of the GMR observed in FeAg films due to the second and third effects has already been reported.¹⁶ As the AgNiFe composition was found to be constant for all thicknesses the first effect could be eliminated.

To investigate the second, the GMR was modeled assuming an ensemble of superparamagnetic particles whose diameters are given by a log-normal distribution. This size distribution has previously been found to accurately describe the magnetization of SiO₂/Fe sputtered films.¹⁷ A similar approach has also very recently been found to accurately fit the hysteresis of melt-spun Co–Cu ribbons.¹⁸ Assuming the ensemble of particles is noninteracting and above its blocking temperature, the system can be described by set of Langevin

FIG. 1. GMR of five representative NiFe(200 Å)/AgNiFe (\times Å)/NiFe(200 Å) films. The solid lines are fits using the model and parameters described.

functions. This is found experimentally to be the case for the films considered here for temperatures above about 20 K. The magnetization is then found from

$$M = pM_s \sum_{D=1}^{300} f(D) \left[\coth \left(\frac{\mu H}{kT} \right) - \left(\frac{kT}{\mu H} \right) \right], \quad (1)$$

where $\mu = (M_s/6)\pi(D^3)$, $f(D)$ is the log-normal function, and p is the concentration of the ferromagnetic material in the film.¹⁷ In heterogeneous alloy systems the GMR is related to the magnetization by the simple relationship

$$\delta R \propto A(M/M_s)^2, \quad (2)$$

where A is a scaling constant related to the spin-dependent scattering efficiency of the particles.^{2,4,11,13} Using this relationship and the calculated magnetization the experimental data were fitted assuming a constant particle magnetization (the bulk value for Permalloy). The fits are shown as the solid lines in Fig. 1. The size distribution parameters of the fits indicate that the mean particle diameter increased from 14 to 18 Å and that the deviation of the distribution decreased from 0.26 to 0.22 as the AgNiFe film thickness increased from 300 to 2100 Å. From annealing experiments on single AgNiFe films it has been found that variations of this order do not significantly effect the size of the GMR.¹⁹ Variations in the size of the GMR due to changes in the magnetization of the particles could not be determined due to both the very small volume of Ni and Fe in the AgNiFe films and the masking of its hysteresis by the upper and lower NiFe films. This is demonstrated in Fig. 2 which shows hysteresis loops of three of the set of films measured at 10 K.

To remove the effect of current shunting in the NiFe capping films the sandwich resistance was calculated assuming a parallel resistor model. This has been shown to be a

FIG. 2. Hysteresis loops of three representative NiFe(200 Å)/AgNiFe (\times Å)/NiFe(200 Å) films.

reasonable approach, providing the mean free path of the conduction electrons is much less than the thickness of the films.²⁰ This is clearly the case in these films in which the upper and lower NiFe films are 200 Å thick and the maximum AgNiFe thickness is 300 Å and is supported by the excellent straight line fit obtained for a graph of the inverse of the sandwich resistance plotted against the AgNiFe film thickness. In addition analysis of the resistivity of the NiFe films using a simple free electron approach provides a value for the mean free path much less than the thickness and compares well with the spin-up and spin-down electron mean free paths reported for NiFe (110 and 10 Å, respectively).²¹ From this analysis the magnetic contribution to the resistivity was obtained and is shown in Fig. 3. Also shown in this figure is the percentage change of the resistance of the AgNiFe films alone. As can be seen from this figure, the variation of the magnetic part of the scattering with thickness of the AgNiFe films is within the experimental scatter of the results.

IV. CONCLUSION

These results indicate that the thickness dependence of the GMR in AgNiFe heterogeneous alloy films is small when they are placed between two NiFe films. This can be understood by considering the spin-dependent transmission of electrons at the interfaces. Analysis of the GMR of NiFe-based spin valves has shown that electrons are coherently transmitted across NiFe/Cu interfaces.²¹ Thus, it is to be expected that there will be very little spin orbit scattering (and hence spin mixing) at the AgNiFe/NiFe interfaces and hence no reduction in the GMR as the thickness of the AgNiFe is decreased.

A mechanism is described which considers the effect of small magnetic particles on the spin diffusion length in a granular giant magnetoresistive material. Spin depolarization occurs by precession of the spin orientation of the carrier due to the s - d exchange interaction within a magnetic particle. Numerical simulation of this jitterbug effect is found to generate a temperature and field dependence of the distance a carrier may travel within the sample without losing its spin memory. © 1996 American Institute of Physics. [S0021-8979(96)54008-2]

INTRODUCTION

In a granular giant magnetoresistive (GMR) material,¹ the magnetic component consists of small, independent, entities embedded in a nonmagnetic, conducting matrix—usually a combination of two or more suitable immiscible metals such as Co and Ag or NiFe and Ag. Such material may be prepared by a variety of methods such as sputtering, coevaporation, or mechanical alloying. During the application of a magnetic field the magnetic orientation of the particles changes from a random configuration at the zero magnetization point (the origin for a superparamagnetic system, otherwise the coercive point) to alignment at magnetic saturation. As for GMR multilayers² the spin-dependent scattering at the magnetic particles varies as the degree of alignment of the magnetic regions is altered thereby generating a giant magnetoresistance. The temperature dependence of the magnetoresistance is an important clue in unraveling the dominant scattering mechanisms. In this article we describe a new process of spin depolarization which contributes to the temperature and field dependence of this effect.

THE MODEL

The GMR in these materials can be thought of as resulting from a transfer of magnetic information between adjacent magnetic granules which is mediated by the spin memory of the electrical carriers. By analogy with the concept of spin memory in nuclear magnetic resonance,³ the information is coded onto the spin population by the first magnetic granule and then subsequently “read” by the second. This spin information is written by the first magnetic cluster in the form of a divergence of the electrochemical potential for up and down spin channels which arises from spin-dependent bulk and interface scattering. In the former case it takes effect over a characteristic length l_f in the ferromagnetic material given by⁴

$$\frac{1}{l_f^2} = \frac{1}{2\tau_{\uparrow\downarrow}} \left(\frac{1}{D_{\uparrow}} + \frac{1}{D_{\downarrow}} \right), \quad (1)$$

where D_{\uparrow} and D_{\downarrow} are the diffusion coefficients of the respective spin channels in the ferromagnet and $\tau_{\uparrow\downarrow}$ is the spin-flip relaxation length. This expression is therefore dominated by the minority spin diffusion coefficient. For the case of bulk scattering, this would determine a minimum magnetic cluster size for effective spin filtering which contributes to explaining the existence of an optimum magnetic cluster size for maximizing the GMR amplitude.

Magnetic clusters in a granular GMR material thus fall into two classes:

- (1) clusters larger than the critical size that can read and write spin information, and
- (2) smaller particles which are inefficient spin filters (note that these will also have a lower magnetic polarization for given values of magnetic field and temperature).

The latter do not contribute effectively to modifying the electrochemical potentials. In fact, we argue that their contribution to the GMR is a detrimental one in that they increase the effective longitudinal relaxation rate in the paramagnetic matrix between the large spin filter clusters and hence help decrease the spin diffusion length $l'_{sf} = (D'\tau'_{\uparrow\downarrow})^{1/2}$ in the matrix thereby speeding up the spin memory decay.

The evolution of the spin memory in the interim between read and write operations is evidently crucial to determining the observed GMR amplitude since the spin information must survive for sufficiently long that it can be read by the next magnetic cluster. The spin memory relates directly to the spin flip relaxation time $\tau_{\uparrow\downarrow}$ to which a number of processes contribute. For granular GMR material it arises primarily from spin orbit scattering which is not temperature dependent.⁴ The spin diffusion length $l'_{sf} = (D'\tau'_{\uparrow\downarrow})^{1/2}$, which determines the spatial decay of the spin memory, evidently contains the temperature dependence of the diffusion con-

FIG. 1. Variation of l_j (Å) with temperature (K) for a fixed field of 3.1 T and a log normal distribution of particle size with a mean diameter of 15 Å and $\sigma=0.2$.

stant D ; however, experimentally this is insufficient to model the observed temperature dependence of many granular GMR systems. Given the small magnetic particle sizes, magnon scattering seems to be an unlikely candidate and this leads us to search for a supplementary temperature variation which arises from an additional temperature-dependent contribution to the spin-flip scattering rate.

Accordingly we now postulate a new spin-dependent mechanism which contributes to $\tau_{\uparrow\downarrow}$ by virtue of the pseudo-Larmor precession of the carrier spins owing to the $s-d$ exchange interaction in the magnetic component of the inhomogeneous material. It should be noted that the precession which we describe is termed a pseudo-Larmor precession

because it is not associated with the magnetic field within the sample, but involves only the exchange field whose effect is two to three orders of magnitude larger than any imaginable internal magnetic field or indeed any magnetic field that might realistically be externally applied.

The depolarization mechanism that we propose derives from the fact that the exchange fields in the nonmagnetic matrix are small and the situation is thus described by a “sudden” approximation of magnetic resonance in which the spin axis orientation is conserved between magnetic particles.⁵ If the magnetic clusters are thermally misaligned from the applied field direction, the spin carrier “jitterbugs” about these successive misaligned quantization directions by

FIG. 2. Variation of l_j (Å) with field (T) at a fixed temperature of 5 K and a log normal distribution of particle size with a mean diameter of 15 Å and $\sigma=0.2$.

random angles determined by the exchange precession frequency and the time spent in each magnetic region and hence eventually loses its spin memory. The moment and particle diameter are therefore important parameters determining the degree of precession. Reference 6 elaborates the details of the mechanism. It is found therein that the precession is very sensitive to small deviations of the orientation of two successive clusters. This will therefore be particularly apparent at the approach to saturation where thermal fluctuations result in a small off-axis component of magnetization.

By virtue of its contribution to $\tau'_{\uparrow\downarrow}$ in the paramagnetic matrix, the jitterbug spin channel mixing moderates the GMR observed, particularly in the case of small GMR amplitude where the system is more sensitive to small changes in $l'_{sf} = (D' \tau'_{\uparrow\downarrow})^{1/2}$. Since the polarization of the magnetic clusters responsible for the GMR is a function of B/T (in the absence of anisotropy and interactions), the jitterbug relaxation mechanism affects both the temperature and field dependence of the GMR. Experimentally the mechanism increases the temperature dependence of the GMR. In particular, at fixed temperature the effect of jitterbug mixing may be observed experimentally by its effect on the approach to saturation of the magnetoresistance.

NUMERICAL SIMULATION

The effect on the passage of a spin through an assembly of the smaller class 2 magnetic particles has been modeled to investigate the effect on spin memory of applied field and temperature due to the jitterbug spin depolarization mechanism. The numerical simulation calculated the average spin-flip time for a wide range of fields and temperatures, and for a wide variety of log normal distributions of magnetic particle radii. For each distribution, field, and temperature 10 000 spin trials were made and the average flip time calculated from the resulting flipping distribution. For each trial a random sequence of magnetic particle radii was generated in accordance with the specified particle size distribution. For each of these particle sizes a thermal angular deviation from the applied field direction was randomly generated, the probability distribution of this generation being compatible with the spin phase space and the Boltzmann distribution for the particular particle radius. The particles were assumed to be isotropic and sufficiently well separated that interactions could be neglected. From nucleation and phase separation considerations⁷ backed up by transmission electron microscopy evidence⁸ their separations were chosen proportional to the sums of radii of successive pairs.

The log normal distribution of particles was normalized to incorporate all the magnetic material present and hence the matrix is by definition free from all paramagnetic impurities and therefore has no effect on the spin memory of the carrier. We consider the incoming coded spins and follow the

change in the direction of the spins as they encounter successive particles and undergo jitterbug precession within them.

The spin evolution is tracked by alternately applying precession transform matrices to simulate the behavior of the spin in the local exchange field of one magnetic particle, then rotational vector transformation matrices, to shift the spin to the reference frame of the next particle's exchange field. Each spin trial terminated when the total spin deviation constituted 90° from the start direction.

The average spin-flip time was then converted to the distance l_j traveled by an electron within these magnetic regions before having its spin direction rotated by more than 90° by this pseudo-Larmor precession mechanism. Figure 1 shows the form of the decay of l_j with increasing temperature for an array of particles with a mean particle size of 15 Å, $\sigma=0.2$ and an applied field $H=3.1$ T. The form of this curve is of course directly related to the distribution of particle size and can be scaled with B/T . This is further demonstrated in Fig. 2 in which at a fixed temperature and particle distribution l_j increases linearly with field. The actual value of l_j is highly dependent on the particle size and, hence, the details of the particle size distribution.

DISCUSSION

The jitterbug spin depolarization effect has been shown to be an effective spin channel mixing process which through its dependence on particle size is dependent on both temperature and field. In turn by shortening the spin diffusion length it increases the temperature dependence of the giant magnetoresistance.

Modeling effects of temperature annealing on giant magnetoresistive response in discontinuous multilayer NiFe/Ag films

J. O. Oti

National Institute of Standards and Technology, Boulder, Colorado 80303

Y. K. Kim

Quantum Peripherals Colorado, Inc., Louisville, Colorado 80028

The giant magnetoresistive (GMR) behaviors of discontinuous double-layer giant magnetoresistive films with different microstructure arising from different annealing conditions, are calculated using a numerical micromagnetic model. The effect of magnetic grain growths in the perpendicular and lateral directions in the magnetic layers, and the formation and growth of grain clusters were studied. The GMR responses of the films are analyzed in terms of magnetostatic interactions between the magnetic layers and the microstructural geometric effects on the transport properties of the samples. © 1996 American Institute of Physics. [S0021-8979(96)54108-6]

A phenomenological micromagnetic giant magnetoresistance (GMR) model¹ is used to examine the dependence of GMR response on annealing-induced microstructural changes in double-layer NiFe/Ag films having an active area between contact electrodes of $0.42 \times 0.42 \mu\text{m}$. Discontinuous multilayer NiFe/Ag films are attractive as GMR magnetic sensors due to their high sensitivity and low saturation fields.^{2,3} These films are obtained by subjecting sputtered NiFe/Ag films to moderate thermal annealing. The initial effect of annealing is to partially or completely separate the touching NiFe grain boundaries of the unannealed sample by causing the diffusion of Ag into the grain boundaries. This reduces the surface-free energy of the grain boundaries. Other effects of annealing, such as the formation of grain clusters within the magnetic layers, and bridging of the grains of the magnetic layers through the Ag spacer layer, may occur at high annealing temperatures.² These result in further reduction in interfacial and grain boundary energies. Changes in the microstructure of the sample affects the GMR behavior of the films.

In this paper, the effects of the diffusion of Ag into grain boundaries and the formation of grain clusters are modeled separately to isolate the effect of each mechanism. The microstructural dimensions of the sample are chosen in the calculations so that the volume and active area of the sample remain the same or as close as possible to their unannealed values. Two possible mechanisms of cluster formation following an initial Ag diffusion are considered. These are lateral grain growth within a magnetic layer, and the formation and growth of grain clusters. Simulation of clusters in our model by combining grains of a magnetic layer is illustrated in Fig. 1. The grains within a cluster are exchange-coupled to each other, while the remaining grains of the sample are not.

The micromagnetic GMR model¹ calculates the total resistance of a sample from a given magnetization distribution in the sample. The distributions are obtained by using a model⁴ in which each magnetic layer is divided into a rectangular array of uniformly magnetized discrete elements having square cross sections of length D in the plane of the sample. The elements simulate the magnetic grains of the sample and in general are not touching. The magnetic layers are characterized by distributions of exchange, anisotropy,

and magnetostatic parameters among the grains. The magnetic moment of each grain is allowed to dynamically relax in three dimensions, in the presence of an external field and effective exchange, magnetocrystalline anisotropic, and magnetostatic internal fields. Each grain is characterized by an intrinsic mean resistivity ρ_0 that is modified by an amount $\delta\rho(M)$ due to the magnetization of the medium. This change in resistivity has intralayer and interlayer components representing spin-dependent electron scattering within a magnetic layer and between layers. These components depend on the microstructural and transport properties of the sample, and are proportional to the cosine of the angles between the magnetization of a grain and those of its nearest neighbors.

The magnetic layers considered in this article have the same magnetic properties and linear dimensions, which simplifies the form of the defining equations. In addition, intralayer scattering is assumed to be negligibly small compared to interlayer scattering and is therefore omitted in this treatment. The expression for grain resistivity in this case is given by¹

$$\rho = \rho_0 + \delta\rho(M) = \rho_0[1 + \chi\alpha(1 - \hat{\mathbf{m}} \cdot \hat{\mathbf{m}}')], \quad (1)$$

FIG. 1. Plan view of cluster pattern used in calculations. The small squares represent the grains of the sample. The shaded regions represent grains that are combined to form clusters. The clusters in the figure have four grains on the side.

where α is an interlayer probability scattering parameter defined as

$$\alpha = \frac{D^2}{(2A - D)^2} e^{-d/\lambda} = Q e^{-d/\lambda}. \quad (2)$$

χ is a material-dependent cofactor, $\hat{\mathbf{m}}, \hat{\mathbf{m}}'$ are unit magnetization vectors of a grain and its nearest neighbor in the adjacent magnetic layer, λ is a model-dependent characteristic transport length, A is the distance between the centers of adjacent grains within a magnetic layer, and d is the separation between the magnetic layers. α embodies the dependence of resistivity on the microstructural geometric and transport properties of the sample. Q , which is the geometric term, defines an *incidence cross section*, which represents the fraction of the incidence polarized electron flux in the spacer region that scatters off magnetic grain boundaries. The exponent in Eq. (2) is the transport term and expresses the attenuation of polarized electron flux in the spacer region due to diffusion. λ is in general a tensor, but for simplicity we treat it here as a simple scalar.

In the CIP direction (x direction in Fig. 1), each grain has a resistance of ρ/t . For a given magnetization state of the sample, the resistance of a magnetic layer is obtained by summing the resistances of the grains serially in the direction of current and reciprocally, transverse to the current, in the plane of the sample. The total resistance of the sample is obtained by summing reciprocally the resistances of the magnetic layers.

All the annealed samples studied in this article were assumed to have been derived from an unannealed sample having grain size $D=A=21$ nm, grain thickness $t=2$ nm, and nonmagnetic spacer thickness $d=4$ nm. These dimensions are typical for NiFe/Ag GMR multilayers.^{2,3} Each magnetic layer of the unannealed sample was simulated by a 20×20 array of grains for an active sample area of $0.42 \times 0.42 \mu\text{m}$. The samples were elongated along the direction of current flow by imposing periodic boundary conditions in this direction. The microstructure and number of grains of the annealed samples were chosen to preserve the size and volume of the active area of the sample at their unannealed values.

The magnetization of the grains was chosen at random from a 80 kA/m interval centered about a mean value of 800 kA/m (10 kG). Each grain was characterized by a uniaxial magnetocrystalline anisotropy strength of $8 \times 10^2 \text{ J/m}^3$, and the orientations of the easy axes were varied randomly in three dimensions from grain to grain. A resistivity of $\rho_0=1$ (in arbitrary units), a cofactor of $\chi=1$, and a transport length of $\lambda=10$ nm (assumed independent of annealing) were used in the simulations. GMR response curves were calculated for uniform in-plane transverse fields (parallel to the y axis in Fig. 1).

The following three cases of the possible effects of annealing were simulated:

- (i) Continuous diffusion of Ag into the grain boundaries, which results in a steadily declining grain size $D=21-16$ nm, increasing gap length $G=A-D=0-5$ nm between adjacent grains, increasing grain thickness $t=2-3.4$ nm, and decreasing spacer thick-

ness $d=4-3.5$ nm. Grain growth is therefore normal to the film plane and grain array size is $N=20$.

- (ii) Lateral grain growth occurs beginning with a sample of case (i) having grain size $D=18.5$ nm ($G=2.5$ nm, $t=2.6$ nm, $d=4.3$ nm). This sample corresponds to predicted peak GMR response for case I (see below). Microstructural modifications are simulated by uniformly increasing G and D ($D/G=0.135=\text{const}$), while keeping t and d fixed. The grain array sizes decrease ($N=20-10$) in order to preserve the area and volume of the sample at their unannealed values. It was not always possible to match areas and volumes of the samples exactly with unannealed ones, since the micromagnetic model is incapable of simulating fractional grains.
- (iii) Grain clusters form in the sample starting from the $D=18.5$ nm sample of case (i). Cluster patterns similar to that shown in Fig. 1 are used in the calculations. Clusters of 2 through 6 grains on the side are considered to simulate cluster growth. Two sets of clusters are considered in which intralayer exchange fields⁴ per nearest neighbor of 1.3 and 1.6 kA/m are applied inside the clusters.

The maximum of the GMR curve of a sample $[\Delta R/R]_{\text{max}}$ corresponds to the largest misalignment between the magnetization of corresponding grains in the magnetic layers during the magnetization reversal. This misalignment can be quantified by defining an interlayer correlation factor C that is equal to the average scalar product of the unit magnetization vectors of corresponding grains of the magnetic layers. C varies from +1 to -1 for complete parallel and antiparallel mutual orientation of the magnetization of the layers.

Calculated $[\Delta R/R]_{\text{max}}$, maximum correlation factor C_{max} , and scattering cross section Q for cases (i) and (ii) are plotted as functions of gap length G in Fig. 2. Inflated $[\Delta R/R]_{\text{max}}$ values arise from the arbitrary choice of ρ_0 and χ . For case (i) C_{max} and Q decrease monotonically with G , and C_{max} eventually saturates at -1. C_{max} decreases as the local magnetostatic coupling between corresponding grains of the layers increases and this has the effect of increasing the GMR response. A decreasing Q , on the other hand, lowers the GMR response, because the flux of spin-polarized electrons that couples the nearest-neighbor grains in the magnetic layers diminishes. $[\Delta R/R]_{\text{max}}$ attains a peak value at around $D=18.5$ nm when these opposing effects combine optimally. After C_{max} saturates, $[\Delta R/R]_{\text{max}}$ becomes solely dependent on the continually decreasing Q . The exponent in Eq. (2) has a negligible effect during these transformations owing to the small variation in the interlayer separation d . For Case II, Q remains constant for $D>18.5$ nm, so $[\Delta R/R]_{\text{max}}$ again depends on the variation of C_{max} alone. Increasing G causes C_{max} to decrease until it eventually saturates at -1. This causes $[\Delta R/R]_{\text{max}}$ to increase until saturation as well.

The presence of clusters in case (iii) complicates the magnetization processes more. Conceptually the clusters may be regarded as larger grains whose internal exchange

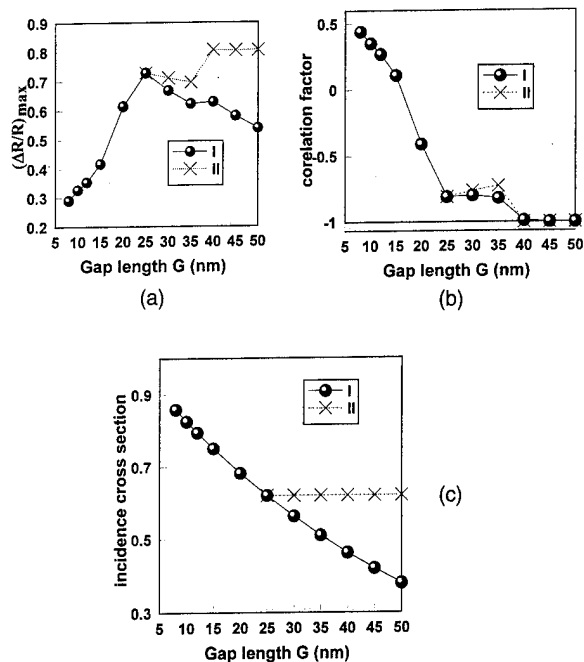

FIG. 2. Dependence of (a) maximum GMR response $[\Delta R/R]_{\max}$, (b) maximum correlation factor C_{\max} , and (c) scattering cross section Q on gap length G , for cases (i) and (ii) described in the text. The plotted values of GMR are arbitrary due to the arbitrary choices of resistivity $\rho_0=1$ and co-factor $\chi=1$.

coupling enables their magnetization to rotate more easily towards an applied field. This tendency increases with exchange coupling. Because of the difference in the properties of the clusters and the surrounding nonexchange-coupled grains, the clusters act as natural nucleation sites for the magnetization reversal of the sample as a whole. At low external fields, interlayer magnetostatic interactions between the clusters promote the misalignment of their magnetization in the layers. This is evident from Fig. 3(a), which compares C_{\max} for the two sets of samples having clusters with internal exchange fields of 1.3 and 1.6 kA/m.

Clusters act as sources of additional domain noise. This is a consequence of jumps in the magnetization reversals of the clusters due to magnetostatic interactions. This behavior can be seen in the calculated magnetization curves of the magnetic layers of a sample with five-grain cluster sizes and exchange field 1.3 kA/m shown in Fig. 3(b). Also plotted in the figure is the GMR response curve of the sample. The magnetic properties of the layers are statistically similar, but not point-to-point identical. Their mutual interactions may thus result in completely different reversal modes in the magnetic layers. As a large positive external field acting on the sample is reduced, the magnetostatic interactions between the layers cause M2 to switch negatively at low fields, so as to attain an antiparallel orientation relative to M1. When the field is increased in the negative direction and M1 is switched negatively, magnetostatic interactions forces M2 to again switch positively.

In this paper we have used a phenomenological GMR model to examine simple models of the microstructural changes brought about by annealing and their effects on the GMR responses of discontinuous NiFe/Ag multilayers.

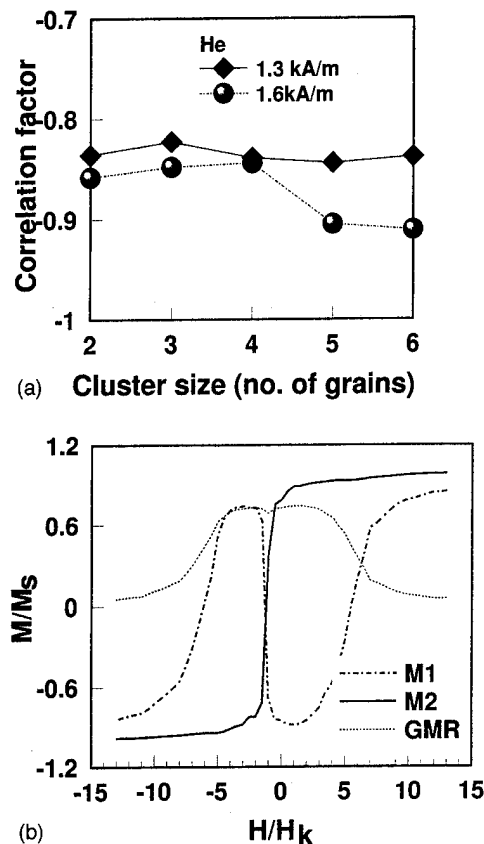

FIG. 3. (a) Maximum correlation factor C_{\max} as a function of cluster size, for two sets of samples with exchange fields in the clusters of 1.3 and 1.6 kA/m; (b) magnetization curves (M1 and M2) of magnetic layers and GMR response curve of a sample with five-grain clusters and cluster exchange coupling fields of 1.3 kA/m.

These changes have been considered separately to isolate their various impacts on the GMR responses. A formulation of the model, that assumes that intralayer spin-dependent electron scattering is negligible compared to interlayer scattering, is used. Variations of the considered microstructural features of samples will exist simultaneously in real materials, and their evolutions with annealing temperature will proceed according to a variety of laws other than those considered here. Additional effects due to sample sizes and a greater number of magnetic layers than the two considered here will also be important. However, several important conclusions follow from the simple picture we have presented. Grain-growth mechanisms that increasingly separate grains within a magnetic layer generally promote greater misalignment of the magnetization of the layers due to magnetostatic interactions. This has a tendency to increase the GMR, but may be opposed by other transport properties of the sample such as reduced polarized-electron flux in the sample. Grain clusters act as natural nucleation centers in a sample and generate additional noise.

Magnetoresistance (MR) behavior in melt-spun ribbons of a $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ alloy has been studied. The rapid solidified ribbon, when properly heat treated for phase decomposition, exhibits giant magnetoresistance behavior with the MR values of 8.5% at room temperature and 29% at 4.2 K. The observed magnetoresistance in the alloy is attributed to spin-dependent scattering at the two-phase interface and in the ferromagnetic phase. The substantial increase in MR, as the temperature decreases from room temperature to 4.2 K, is most likely caused by the reduction of spin-flip scattering of conducting electrons in the paramagnetic regions as a result of magnetic transformation. © 1996 American Institute of Physics. [S0021-8979(96)54208-2]

I. INTRODUCTION

Cu-Ni-Fe alloys are known to decompose, upon appropriate heat treatment, into Cu-rich and (Ni,Fe)-rich phases.^{1,2} We have previously reported the magnetoresistance (MR) behavior of $\text{Cu}_{60}\text{Ni}_{20}\text{Fe}_{20}$ (wt %) alloy spinodally decomposed into an extremely fine scale two-phase microstructure.^{3,4} In the present work, a $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ alloy, which is presumably outside the spinodal region, has been rapidly solidified by melt-spinning technique and subsequently heat treated at elevated temperatures in order to obtain a very fine two-phase microstructure. The MR behavior of so-processed Cu-Ni-Fe alloy ribbons is reported.

II. EXPERIMENTAL PROCEDURES

$\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ (in wt %) ribbons were prepared by conventional melt spinning and rapid solidification process in an argon atmosphere using a copper wheel rotating at a surface speed of ~50 m/s. The ribbons were 2 mm wide, 20–30 μm thick, and 10–15 cm long. The melt-spun ribbons were sealed in quartz tubes, and annealed at 400 °C for 24 h to modify the microstructure.

X-ray diffraction (XRD) analysis with $K\alpha$ (Cu) radiation was used to characterize the structure of the ribbons. Magnetic measurement was carried out by using a vibrating sample magnetometer (VSM) and superconducting quantum interference device (SQUID) magnetometer with the applied field up to 6 T. The magnetoresistance (MR) of the ribbons was measured by using the four-point technique with a magnetic field of 6 T applied in the ribbon plane.

III. RESULTS AND DISCUSSION

The structure of the melt-spun $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ (in wt %) ribbons was investigated by using XRD. The x-ray diffraction analysis shows essentially single phase like but somewhat broadened Bragg peaks of (111), (200), (220), (311), and (222). This suggests that the as-spun $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ ribbon is polycrystalline, and the compositional inhomogeneity and phase separations in the material are small. After anneal-

ing at 400 °C for 24 h, splitting peaks coming from the Cu $K\alpha_2$ diffraction appears at higher diffraction angles, which are related to the improved crystal quality of the ribbon as a result of the aggregation and growth of the extremely fine ferromagnetic (Fe,Ni)-rich phase from the Cu-rich matrix and the stress relief of the microstructure.

Shown in Fig. 1 is the magnetization behavior of the melt-spun ribbon at room temperature and 4.2 K, measured with the maximum field of 6 T. The ribbon exhibits a very small hysteresis and magnetization of only 5 emu/g even at a field as high as 6 T. The observed increase in magnetization by 160% when the field is raised from 1 to 6 T and the presence of a slope at 6 T indicates that the ribbon sample was still not fully saturated at 6 T. This suggests that a very fine-scale, ferromagnetic (Fe,Ni)-rich phase, at least partially separated by a paramagnetic phase around the ferromagnetic phase, could have been formed in the course of the melt-spinning process. The magnetization increases as the temperature is lowered. A substantial ferromagnetism appears for the as-spun ribbon at 4.2 K. The M - H loop shows a hysteresis with a remanence ($M/M_6\text{ T}$) of ~0.38, coercivity

FIG. 1. M - H loops for the as-spun $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ ribbons.

FIG. 2. Temperature dependence of magnetization ($H=100$ Oe) of the as-spun and annealed $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ ribbons.

of ~ 300 Oe and saturation magnetization of 16 emu/g at 6 T. After annealing, the room-temperature magnetization behavior of the ribbon is quite different from that of the as-spun sample. The annealed ribbon shows a hysteresis with a remanence ($M/M_6\text{ T}$) of ~ 0.05 , coercivity of less than 50 Oe, and a higher saturation moment of 14 emu/g at 6 T. A similar magnetization behavior is observed at lower temperatures by the annealed ribbon. The dependence of the magnetization behavior on the annealing process is a consequence of the change of microstructure during an annealing treatment which enhances the phase separation process of the Cu-rich and (Fe,Ni)-rich phases as well as the stress relief process in the melt-spun ribbon.

Figure 2 represents the zero-field-cooled (ZFC) and field-cooled (FC) magnetization curves (at $H=100$ Oe) for the as-spun and annealed $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ ribbons. It can be noticed that no divergence is observed between ZFC and FC plots for the as-spun $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ ribbons until the ZFC peak. A large discrepancy in magnetization between two curves occurs at temperatures below about 50 K. The observation of thermal hysteresis around the peak of the ZFC curve indicates the limited distribution in the size and shape of the magnetic phase. It is also deserved to notice the large increase in the magnetization values at 100 Oe as the temperature decreases from room temperature. Such substantial increase in magnetization is also found in the FC and ZFC curves measured at 1000 Oe. Upon annealing, the higher temperature of thermal hysteresis (~ 250 K) and broaden maximum peak in ZFC curve reveals the particle growth as well as the increased size distribution of the ferromagnetic phase. From the above results of magnetization behavior measurements, we believed that the magnetic behavior of the $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ ribbons is related with both paramagnetic and superparamagnetic contributions. The superparamagnetic behavior comes from the ferromagnetic (Fe,Ni)-rich phase which are randomly coupled, whereas the paramagnetic be-

FIG. 3. Field dependence of MR ratio at room temperature and 4.2 K for the as-spun and annealed $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ ribbons.

havior is associated with the paramagnetic regions around the ferromagnetic phase, which exhibit Curie temperatures below room temperature.

Shown in Fig. 3 are the magnetoresistance (MR) ratio versus applied field curves of the melt-spun and annealed ribbons. The MR ratio was defined here as $\Delta\rho_m/\rho_s$ or $\Delta R_m/R_s$, where ρ_s (or R_s) is the electrical resistivity or resistance near the saturation field. All the MR effect reported here is negative. In the as-spun ribbon, the resistance at room temperature decreases continuously up to the maximum field of 6 T and gives a MR ratio of 3%. At 4.2 K, the MR ratio drastically increases to 26%. The MR ratio versus applied field curves do not saturate in magnetic fields up to 6 T at both temperatures, indicating that the MR values will be higher if the applied field is increased. The annealing treatment of the melt-spun ribbon at 400 °C for 24 h significantly enhances the room temperature and 4.2 K MR ratios to 8.5% and 29%, respectively. Such dependence of MR ratio on the annealing process is believed to be mostly related to the changes in microstructure. Similarly as in the as-spun ribbon, the MR ratio in the annealed ribbon does not saturate at $H=6$ T, and hence the maximum attainable MR ratio must be higher than the 29% measured at 6 T.

Figure 4 shows the dependencies of MR ratio, resistivity (ρ), and field-induced change in resistivity ($\Delta\rho_m$) on temperature for the as-spun and annealed ribbons. In contrast to the temperature dependence of magnetoresistance of deformed $\text{Cu}_{60}\text{Ni}_{20}\text{Fe}_{20}$ alloys,⁴ the ribbon shows a significant increase in the MR ratio of a factor of almost 9 upon cooling from room temperature to 4.2 K [see Fig. 4(a)]. This could be interpreted in terms of relatively strong temperature-dependent increase in $\Delta\rho_m$ by a factor of ~ 4 combined with a weaker temperature variation of resistivity. As discussed below, the magnetoresistance of the $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ ribbons is likely related to the spin-dependent scattering between neighboring ferromagnetic phases and magnetic fluctuation scattering.

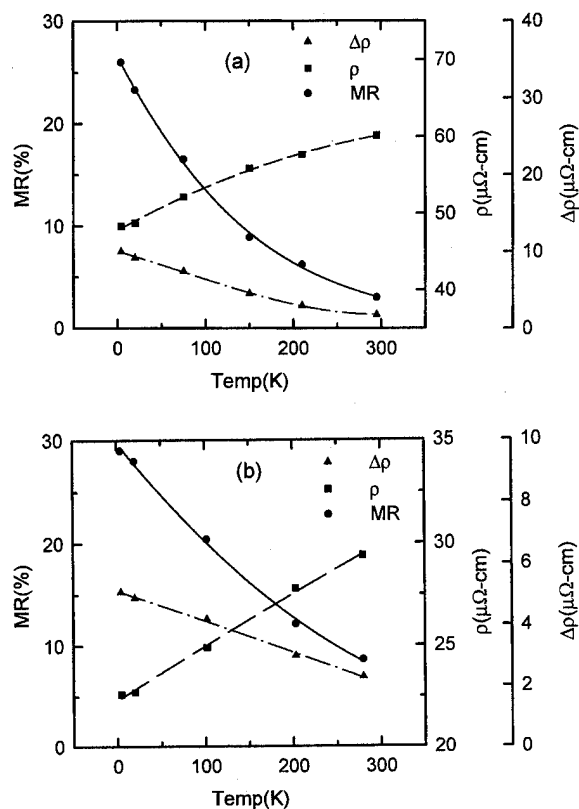

FIG. 4. Temperature dependence of MR, ρ and $\Delta\rho$ for the $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ ribbons, (a) as-spun and (b) after annealing at 400 °C for 24 h.

In our previous report,⁴ the MR of a deformed $\text{Cu}_{60}\text{Ni}_{20}\text{Fe}_{20}$ alloy could be mostly attributed to the magnetic excitation in the nearly superparamagnetic alloys, which are suppressed by an applied field and lead to the decreasing MR ratio as the temperature is lowered. The spin-dependent scattering appears to play only a relatively minor role in the magnetoresistance of deformed alloy. However, the MR in the present melt-spun $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ ribbon seems to be dominated by the spin-dependent scattering, as well as the magnetic fluctuation scattering. As shown in Fig. 3, the room-temperature MR curve for the as-spun $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ ribbon consists of gradual and almost linear decrease from zero field to 6 T, which could be caused by the local magnetic fluctuations, such as extremely fine ferromagnetic particles or paramagnetic regions with Curie temperature well

below room temperature, which leads to the strong electron scattering. At 4.2 K, a rapid drop in resistance at low fields appears in the MR curve (Fig. 3), which is then followed by a gradual decrease at higher fields. The large initial drop in resistance at low fields is probably related to the spin-dependent scattering at the two-phase interface and in the ferromagnetic phase, similar by as reported for the GMR superlattice structures.⁵ As the temperature decreases, more paramagnetic-like regions in the as-spun ribbon become ferromagnetic and make more contribution to the spin-dependent scattering. Such magnetic-transformation related thus leads to an increase in MR for the $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ ribbon as the temperature is lowered.

After annealing, the contribution of spin-dependent scattering to the MR behavior is increased because of the presence of phase separation into the Cu-rich and (Fe,Ni)-rich phases, which creates more ferromagnetic regions in the microstructure, as well as the stress relief of the microstructure. This is evidenced by the obvious drop in room temperature resistivity at low fields (see Fig. 3). The higher $\Delta\rho_m$ combined with lower ρ after annealing thus results in an increase in the room-temperature MR ratio almost by a factor of ~ 3 (from 3% to 8.5%).

IV. SUMMARY

Melt-spun ribbons of the $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ alloy exhibit giant magnetoresistance behavior when properly heat treated for phase decomposition into Cu-rich and (Fe,Ni)-rich phases. The MR values in annealed $\text{Cu}_{80}\text{Ni}_{10}\text{Fe}_{10}$ ribbons are 8.5% at room temperature and $\sim 29\%$ at 4.2 K at $H=6$ T. The MR behavior in the alloy is mainly attributed to the spin-dependent scattering at the two-phase boundary and in the ferromagnetic phase.

Giant magnetoresistance properties in multilayered Co-Ag/Cu granular alloys

Makoto Iijima, Yutaka Shimizu, Naomi Kojima, Atsushi Tanaka, and Kazuo Kobayashi
Magnetic Materials & Devices Laboratory, Fujitsu Laboratories, Ltd., 10-1 Morinosato-Wakamiya,
Atsugi 243-01, Japan

In this article, we introduce a novel Co-rich Co-Ag/Cu granular alloy structure with increased magnetic sensitivity, and report on our study of the relationship of giant magnetoresistance (GMR) and magnetic properties to annealing temperature and Cu thickness in sputtered $\text{Co}_{66}\text{-Ag}_{34}/\text{Cu}$ multilayered films. We heat treated Co-Ag/Cu films with Cu spacer thickness ranging from 15 to 50 Å up to 500 °C, and found that the MR ratio loosely depends on both the Cu spacer thickness and the annealing temperature, peaking at 7.6% with a 25 Å Cu layer and an annealing temperature of 280 °C. Based on the magnetic properties we observed, as well as x-ray studies, we found that Cu spacers at least 25 Å thick are able to separate the Co-Ag magnetic layers. Our data also indicated that the annealing treatment changed the coupling of magnetic layers from ferromagnetic to antiferromagnetic. The high thermal stability and the high magnetic sensitivity suggest potential use of our novel multilayered structure in applications as magnetic sensors. © 1996 American Institute of Physics. [S0021-8979(96)54308-9]

I. INTRODUCTION

There has been a great deal of research into granular giant magnetoresistive (GMR) structures because of their high MR ratios and their magnetic behavior.¹⁻³ Granular GMR structures consist of a matrix of nonmagnetic metals (such as Ag, Cu, or Au) containing small particles of magnetic metals (such as Co, Fe, or Ni). A granular GMR structure has a high MR ratio (up to 50% at room temperature), and has high thermal stability. These properties are important when granular GMR structures are used in applications such as magnetic read heads. However, a granular GMR film needs several kOe of external magnetic field to change its resistivity, making it difficult to apply in practice.

There have been some attempts at enhancing GMR properties by layering or by optimizing of the size of magnetic particles.^{4,5} These methods have improved the MR ratio, but the saturation fields are still in the range of several kOe. We tried to use a multilayered Co-Ag granular alloy with Ag spacer layers for magnetic sensor applications. Electron microscopy observation revealed that Ag spacer layers shrank, even in the as-deposited state. This makes the layering structure imperfect. Because of our interest in layer separation, we changed the spacer material to Cu, which does not shrink as much as Ag. In this paper we introduce a novel structure for a Co-rich Co-Ag/Cu film which increases the field sensitivity, and discuss the contributions of Cu thickness and annealing temperature to the MR properties.

II. EXPERIMENTAL METHODS

To determine the appropriate Co content for the Co-Ag granular alloys, we have previously investigated the dependence of MR ratio and the saturation field on the Co content. We found that about 40 at. % Co is appropriate for the Co-Ag granular monolayer to achieve a high MR ratio, while about 66 at. % Co for the multilayered Co-Ag/Cu granular is best for lowering the necessary saturation field strength (Fig. 1). We therefore investigated the GMR properties of a Co-

Ag/Cu multilayered film with 66 at. % Co for this article. The 66 at. % Co-Ag (20 Å)/Cu ($t=15-20$ Å) films were deposited onto a Pyrex substrate by dc magnetron sputtering with an argon pressure of 0.1 Pa. The granular layer was deposited from a $\text{Co}_{50}\text{Ag}_{50}$ binary alloy target with Co chips. The composition of the granular layer was determined by ICP-AES analysis. The multilayered structure had ten bilayers (pairs of Co-Ag granular layer and Cu spacer). The sputtered sample was split into 8×8 mm chips.

The annealing was performed in a vacuum at less than 5×10^{-8} Torr, and the samples were held at 200–400 °C for 1 h. Throughout the sample fabrication processes magnetic treatment was not carried out.

We measured magnetoresistivities using the conventional dc four-probe method with a maximum magnetic field of 1 kOe. We defined the MR ratio as $(\rho_{Hx} - \rho_{H1k})/\rho_{H1k}$, where ρ_{Hx} is the resistivity of the film to any external mag-

FIG. 1. The MR ratio (dashed line) and saturation field (solid line) dependence on the Co contents of conventional Co-Ag films (triangles) and multilayered Co-Ag/Cu films (circle). Note that scale of H_s is in \log_{10} .

FIG. 2. The MR curves of Co-Ag (20 Å)/Cu (25 Å) films.

netic field, and ρ_{H1k} is the resistivity to an external field of 1 kOe. External magnetic fields were applied parallel to the current.

We measured magnetization curves using a vibrating sample magnetometer with a maximum applied field of 1 kOe. External fields were applied parallel to the plane. We observed interfaces between the granular and spacer layers with low-angle x-ray diffraction (LAXRD). LAXRD mea-

FIG. 4. LAXRD spectra of Co-Ag (20 Å)/Cu (40 Å) multilayered films. Each spectrum are normalized with maximum peak.

surements were conducted at 2θ angle of up to 4° . All fabrication and measurements were performed at room temperature.

III. EXPERIMENTAL RESULTS

We found that the MR ratio of Co-rich Co-Ag/Cu films depended on both the annealing temperature and the Cu spacer thickness. The MR ratio for the as-deposited film was about 1%, and increased with the annealing temperature up to the maximum of 7.6% at 280 °C, then decreased at 350 °C (Fig. 2). The Cu spacer thickness loosely affected the MR ratio of the film, which peaked in the range from 25 to 40 Å [Fig. 3(a)].

As the Co-Ag as-deposited film was metastable and random mixed state, Ag and Co atoms on the Co-Ag and Cu interface, which results in small MR ratio. The annealing treatment separates Co-Ag alloy into Co and Ag. Separated Co grains in the Ag-rich Co-Ag matrix result in forming the interfaces between Co grain and Cu spacer, which increased the MR ratio. The dependence of MR ratio on Cu thickness suggest that there is some magnetic coupling between the adjacent Co-Ag magnetic layers, but due to the inhomogeneous magnetic layer mentioned above may make the magnetic coupling loose.

Although the saturation field strength (H_s) for the Co-Ag/Cu films varied with the annealing temperature at the films for Cu thickness less than 20 Å, it decreased with the

FIG. 5. Magnetization curves of Co-Ag (20 Å)/Cu (40 Å) multilayered films.

FIG. 6. Cross-sectional TEM images of Co-Ag (20 Å)/Cu (40 Å) multilayered films. (a) As-deposited, (b) annealed at 280 °C.

Cu spacer thickness at Cu thickness over 25 Å, and showed almost the same value around 70 Oe [Fig. 3(b)]. It seems that Cu films less than 20 Å have many pinholes, and therefore Co-Ag magnetic layers connect each other through the pinholes, which result in high H_s like a conventional granular alloys. On the other hand, Cu spacers over 25 Å are able to separate the Co-Ag magnetic layers, which causes weak magnetic coupling. High annealing temperature over 350 °C makes H_s larger. We assumed it is because the roughness of the Co-Ag/Cu interface increased by the interdiffusion of Co atoms into Cu layers, and multilayered film changed to a modulated granular-like structure.

The magnetization curves of Co-Ag/Cu multilayered films changed with the annealing temperature (Fig. 4). The slopes of the magnetization curves show that ferromagnetic coupling is dominant in as-deposit Co-Ag magnetic layers, which changes to weak antiferrocoupling at 280 °C. The

magnetization curves also suggested that the coupling became modulated granular-like after the annealing at 350 °C. The saturation magnetization of the films decreased with the annealing temperature because Co atoms diffused into Cu layer and lose their magnetic moments as mentioned above.

The LAXRD spectrum indicated that although the layering structures damaged at the annealing temperature above 260 °C, they were maintained even at annealing temperature up to 350 °C (Fig. 5). The intensity of a maximum peak at 1.5° (first peak) decreased after annealing at above 260 °C, and second peak at 2.8° disappeared at the same annealing temperature, which indicates that roughness of interfaces are increased because of Co grain growth in the Co-Ag magnetic layers. The annealing treatment over 350 °C increase the roughness of magnetic/nonmagnetic interfaces because of diffusion of Co into Cu layers.

The Co-Ag/Cu multilayered structure was clearly observed with the transmission electron microscopy in the as-deposited state, while it almost disappeared after 280 °C annealing although the layered structure was still observed in the LAXRD spectrum [Figs. 6(a) and 6(b)]. These results are the evidence showing that the roughness of the Co-Ag/Cu interfaces increased by the annealing.

IV. CONCLUSION

By layering the Co-Ag granular film with Cu, we have developed the multilayered structure with high sensitivity. The MR of our novel multilayered Co-rich (66 at. % Co) Co-Ag/Cu film structure depends weakly on the Cu spacer thickness and the annealing temperature, which shows MR ratio of 7.8% and H_s of 70 Oe at 25 Å Cu spacer and annealing at 300 °C. In as-deposited Co-Ag magnetic layer which showed small MR ratio around 1%, a ferromagnetic coupling is dominant, and it changed to weak antiferromagnetic coupling after annealing at 280 °C and showed large MR ratio around 7%. However, by annealing at high temperatures over 350 °C MR ratio decreased and H_s increased because of the diffusion of Co atoms into Cu spacers, which result in increased roughness of the interface between Co-Ag magnetic layers and the Cu spacers.

The high thermal stability and the high magnetic sensitivity suggest the potential of our novel multilayered structure for the practical application as magnetic sensors.

Modeling giant magnetoresistance and magnetization of $\text{Ag}_{1-x}\text{Ni}_x\text{Fe}_y$ heterogeneous alloy films (abstract)

J. Wiggins, M. L. Watson, and P. A. Gago-Sandoval

We have investigated the effects of the particle size distribution on the giant magnetoresistance (GMR) and magnetization of $\text{Ag}_{1-x}\text{Ni}_x\text{Fe}_y$ heterogeneous alloy films both experimentally and through computer simulation. The samples were prepared by sputtering from a mosaic target onto glass substrates at the system ambient temperature. They have thicknesses in the range of 100–300 nm and were rapidly thermally annealed at up to 750 °C to promote phase segregation. The resistivity and magnetoresistivity have been measured in the temperature range 4–300 K in fields of up to 12 kOe and the magnetization by vibrating sample magnetometer at fields of up to 6 T. We have modeled the magnetization and GMR of the system using an ensemble of superparamagnetic particles which have a log normal distribution of diameters. We obtain an excellent fit to the experimental magnetization data at room temperature. This is true for all annealing strategies used. Conversely, we have found a marked difference between the modeled and experimental GMR data for higher temperature annealing strategies. It can be shown that this model accurately fits the magnetoresistance if only particles under a critical diameter are considered. For $\text{Ag}_{1-x}\text{Ni}_x\text{Fe}_y$ heterogeneous alloy films this critical diameter has been calculated to be 6 nm. Larger particles will contribute only to the magnetization and not the magnetoresistivity. To optimize the magnetoresistance an annealing strategy that favors the creation of particles under this critical diameter is required. © 1996 American Institute of Physics. [S0021-8979(96)60708-0]

Structural evolution in sputtered $\text{Co}_{90}\text{Fe}_{10}/\text{Ag}$ giant magnetoresistance multilayers

The Department of Metallurgical and Materials Engineering and The Center for Materials for Information Technology, The University of Alabama, Tuscaloosa, Alabama 35487-0202

The thermal evolution of structure, giant magnetoresistance (GMR), and magnetic properties in two sequences of sputtered $(\text{Co}_{90}\text{Fe}_{10}/\text{Ag})$ multilayers is presented. Granular-type and "discontinuous" GMR is observed depending on layer thickness. © 1996 American Institute of Physics. [S0021-8979(96)54408-5]

I. INTRODUCTION

In a previous paper¹ we surveyed giant magnetoresistance (GMR) in $\text{Co}_{90}\text{Fe}_{10}/\text{Ag}$ sputtered multilayers as a function of both $\text{Co}_{90}\text{Fe}_{10}$ and Ag layer thicknesses and annealing conditions. We were able to differentiate the observed GMR behaviors depending on geometry and annealing treatment into different categories: (1) granular-type GMR (GGMR) in ultrathin CoFe layered samples (layered-GGMR), (2) as-deposited GMR in thicker CoFe and Ag layered samples that upon annealing becomes (3) discontinuous GMR [(DGMR), as first described by Hylton *et al.* in NiFe/Ag multilayers²], and (4) the absence of GMR originating from antiferromagnetic (AFM) layer coupling. In this paper we focus on two series of multilayers samples with fixed CoFe thicknesses of 12.7 and 7.4 Å and varying Ag thickness. The 12.7 Å CoFe series exhibits DGMR in the thicker Ag range and no GMR when the Ag thickness ranges from ~9 to 30 Å where conventional GMR from oscillating AFM coupling is observed in many other sputtered magnetic/nonmagnetic systems.^{3,4} The 7.4 Å CoFe series displays layered-GGMR that oscillates in magnitude with Ag thickness as has been observed in sputtered Co/Ag multilayers with ultrathin Co layers.⁵

II. RESULTS AND DISCUSSION

The films were dc magnetron sputtered in a computer-controlled system onto glass substrates with a permanent magnet positioned behind each substrate providing a 90 Oe field in the film plane. The geometry of the films is [glass/Ta 50 Å/($\text{Co}_{90}\text{Fe}_{10}$ X Å/Ag Y Å)×20/Ta 120 Å]. Magnetic properties were measured on a vibrating sample magnetometer (VSM). X-ray diffraction (XRD) was performed using Cu $K\alpha$ radiation. The MR measurements were made in the plane of the films using a four-point in-line probe assembly with the current and easy axis of the film both perpendicular to the applied magnetic field. The MR% is defined as $\text{MR}\% = \{[\rho(H) - \rho_{\text{max}}]/\rho_{\text{max}}\} \times 100$, where $\rho(H)$ is the sample resistivity at a given field value and ρ_{max} is the resistivity at the maximum applied field. The anneals were performed in an argon atmosphere. All measurements were made at room temperature. The reported values for the CoFe and Ag thicknesses are based on thickness measurements made using low-angle XRD (LXRD).

Considering first the 12.7 Å CoFe series, Fig. 1(a) shows the MR% for as-deposited and annealed (15 min at 300 and 400 °C) samples as a function of Ag layer thickness. The maximum MR% consistently occurs in samples with thicker

Ag layers. The MR%- H profiles for a sequence of annealing temperatures are shown in Fig. 1(b) for separate (CoFe 12.7 Å/Ag 45 Å) samples. Only one half of the full profile is shown for clarity. Notice the sensitive nature of the profile shape to annealing temperature and the profile sharpening upon annealing at the lower temperatures. This MR behavior upon annealing is characteristic of DGMR, a highly field-sensitive GMR arising from negative exchange coupling between ferromagnetic platelets which are formed by CoFe layer breakup due to Ag diffusion through columnar grain boundaries.² The source of the as-deposited MR is unclear,

FIG. 1. (a) MR% vs Ag layer thickness in as-deposited and annealed (15 min) samples: [7059 glass/Ta 50 Å/(CoFe 12.7 Å/Ag X Å)×20/Ta 120 Å], (b) MR%- H profiles [one half of the field sweep (positive to negative) is shown for clarity], and (c) Hard-axis M - H loops for separate [7059 glass/Ta 50 Å/(CoFe 12.7 Å/Ag 45 Å)×20/Ta 120 Å] samples annealed for 15 min.

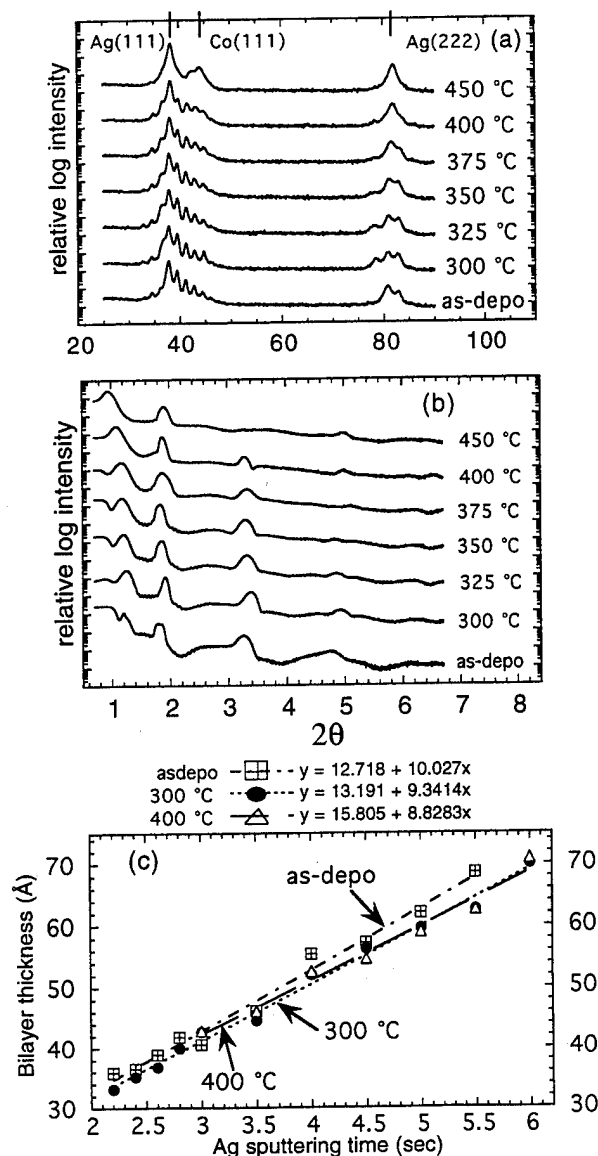

FIG. 2. (a) HXRD scans and (b) LXR D scans vs 15 min anneals on separate [7059 glass/Ta 50 Å/(CoFe 12.7 Å/Ag 45 Å)×20/Ta 120 Å] samples, and (c) plot of measured bilayer thicknesses via LXR D vs Ag deposition time for the CoFe 12.7 Å series.

although it is assumed related to the DGMR. Figure 1(c) shows the hard-axis magnetic hysteresis (M - H) loops for as-deposited and annealed (CoFe 12.7 Å/Ag 45 Å) samples. In-plane uniaxial magnetic anisotropy disappeared in samples annealed at temperatures above 325 °C. Notice the dip in coercivity (H_c) in the 300 °C annealed sample and then the large increase beyond the as-deposited H_c value in the 400 °C annealed sample. This effect is also seen in the MR%- H profiles of Fig. 1(b) where the profile peak position shifts toward zero with low-temperature annealing and then to larger field values beyond the as-deposited value after higher-temperature annealing.

Figures 2(a) and 2(b) are high-angle XRD (HXRD) and LXR D scans, respectively, versus annealing temperature for the (CoFe 12.7 Å/Ag 45 Å) DGMR samples. Satellite peaks around the (111) growth texture are observed in the HXRD scans signifying artificial structural coherency at the inter-

faces [Fig. 2(b)]. Low-angle Bragg peaks observed in the LXR D scans reveal appreciable film layer flatness and periodicity in the multilayers [Fig. 2(b)]. Low-temperature annealing (300 and 325 °C) reveals a slight smoothing and increased coherency of the interfaces as the GMR starts to increase. This is manifested by the initial formation of additional satellite peaks next to both the Ag(111) and (222) peaks in the HXRD scans, and slightly more intense low-angle Bragg peaks in the LXR D scans. This agrees with the literature on sputtered Co/Ag multilayers where "back diffusion" was observed along with a MR% increase upon annealing.⁶ At the "over-annealing" temperatures the artificially layered structure and the interfaces show degradation as only signals from the bulk layers are present in the HXRD scans and the low-angle Bragg peak intensities have decreased in the LXR D scans. There is a slight shift of the low-angle peak positions to higher angles with annealing which corresponds to a decrease in bilayer thickness attributed to film densification from sputtered-in defect elimination and a change in the relative CoFe and Ag layer thicknesses. Figure 2(c) shows a plot of the bilayer thicknesses Λ calculated from LXR D scans for as-deposited and annealed samples. The method used here employs an extrapolation technique described in Ref. 7. The linear fits of Fig. 2(c) allow for the calculation of the average as-deposited CoFe thickness (intercept) of 12.7 Å and the Ag deposition rate (slope) of 10.03 (10.0) Å/s. Annealing results in an apparent increase in the CoFe thickness and an apparent decrease in the measured Ag deposition rate. This is consistent with the idea that Ag diffuses through CoFe grain boundaries resulting in thicker overall CoFe layers (platelets) at the expense of Ag layer thickness, as shown schematically in Fig. 3.

Now we will concentrate on the 7.4 Å CoFe series. Recently, an oscillation in MR% with Ag layer thickness was observed in sputtered (Co 6 Å/Ag x Å) multilayers with the first peak at ~ 18 Å and the second, much broader peak at ~ 40 Å Ag.⁵ This report also states that Co does not form a continuous layer when deposited on Ag until a thickness of at least ~ 8 Å is reached, therefore the GMR and the oscillation are not considered to originate strictly from AFM coupling of complete Co layers, but from Co cluster interactions. Figures 4 and 5 show results from the 7.4 Å CoFe series in which the CoFe layers are not considered continuous. These samples are essentially artificially stratified granular films. The GMR observed is characteristic of single-layer phase separating "granular" alloys (broad MR%- H profiles with very low hysteresis).⁸⁻¹⁰ The as-deposited MR% values versus Ag thickness in Fig. 4(a) show an oscillation in the 7.4 Å CoFe series with peaks at Ag 17.6 and 39.6 Å, respectively, in agreement with Ref. 5. Annealing results in a loss of this oscillation as the MR% decreases nearly monotonically with Ag thickness above 20 Å. Representative MR%- H profiles and M - H loops for as-deposited and annealed 7.4 Å CoFe samples with Ag thicknesses of 17.6 and 39.6 Å are plotted in Figs. 4(b) and 4(c), respectively. Annealing results in squareness loss that is the most pronounced in the Ag 39.6 Å sample annealed at 400 °C.

XRD of the (7.4 Å CoFe/Ag 17.6 Å) samples shows a similar trend in film structure evolution with annealing to

FIG. 3. Schematic of the effect of annealing 12.7 Å CoFe series DGMR films that results in CoFe layer breakup from Ag diffusion through grain boundaries and the subsequent Ag layer thickness decrease and CoFe layer increase.

that observed in the (CoFe 12.7 Å/Ag 45 Å) DGMR samples, where low-temperature annealing (300 °C) results in more distinct satellite shoulder peak formation around the Ag(111) and (222) bulk peaks in the HXRD scan [Fig. 5(a)], and also, the Kiessig fringes from the 20 bilayers are more intense in the LXR scan [Fig. 5(b)]. Annealing at 400 °C degrades the interfaces and increases the relative intensity of the bulk (111) textured peaks at the expense of the satellite peaks.

The as-deposited magnetization (M_s) in CoFe 12.7 and 7.4 Å samples was ~1320 and ~990 emu/cc, respectively, and independent of Ag thickness for both series (M_s of bulk

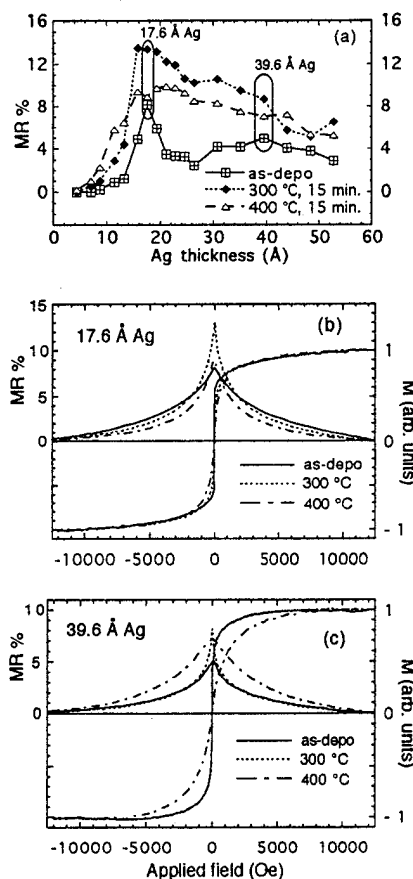

FIG. 4. (a) MR% vs Ag layer thickness in as-deposited and annealed (15 min) samples: [7059 glass/Ta 50 Å/(CoFe 7.4 Å/Ag \times 20/Ta 120 Å)], (b) MR%- H profiles and M - H loops for as-deposited and annealed [7059 glass/Ta 50 Å/(CoFe 7.4 Å/Ag 17.6 Å)×20/Ta 120 Å] samples, and (c) MR%- H profiles and hard-axis M - H loops for as-deposited and annealed [7059 glass/Ta 50 Å/(CoFe 7.4 Å/Ag 39.6 Å)×20/Ta 120 Å] samples.

FIG. 5. (a) HXRD scans and (b) LXR scans vs 15 min anneals on separate [7059 glass/Ta 50 Å/(CoFe 7.4 Å/Ag 17.6 Å)×20/Ta 120 Å] samples.

Co₉₀Fe₁₀ is ~1510 emu/cc). The dependence of M_s on CoFe thickness is indicative of the presence of a magnetically "dead" layer (~1.5 Å). Lower-temperature annealing (300–350 °C) resulted in a small increase in M_s (<10%) in both CoFe 12.7 and 7.4 Å samples. Higher-temperature annealing (~400 °C) reduced M_s ~3–19% below the as-deposited value. The rise in M_s could logically be associated with demixing at the interfaces. However, the drop in M_s after 400 °C annealing is not readily explained (oxidation is a potential explanation but no corroborating evidence has been found for this).

Both the aspect ratio (height/width) and spacing of the CoFe platelets (or clusters) are critical in determining the observed MR behavior. The layered clusters formed during growth in the layered-GGMR samples are considered having a higher aspect ratio than the CoFe platelets formed upon annealing in the DGMR samples. The small difference in CoFe layer thickness reveals a dramatic difference in the observed MR behavior with layered-GGMR samples displaying very broad MR%- H profiles and DGMR samples displaying highly field-sensitive MR%- H profiles.

The American Institute of Physics (AIP) is a not-for-profit membership corporation chartered in New York State in 1931 for the purpose of promoting the advancement and diffusion of the knowledge of the science of physics and its application to human welfare. In order to achieve our purpose, we serve the sciences of physics and astronomy by serving the member societies, by serving individual scientists, and by serving students and the general public.

As leading scientific publishers, the American Institute of Physics and its Member Societies publish more than one-quarter of the world's research literature in all areas of physics including: general physics, applied physics, chemical physics, geophysics, plasmas and fluids, medical physics, nuclear and particle physics, astronomy, electronics, engineering, crystallography, instrument science, materials science, mathematics, acoustics, rheology, optics, and vacuum science. AIP publishes its own archival and translation journals, and provides publishing services to member and other organizations.

Member Societies

The American Physical Society
Judy Franz, Executive Officer
One Physics Ellipse
College Park, MD 20740-3844

Optical Society of America
David W. Hennage, Executive Director
2010 Massachusetts Avenue, N.W.
Washington, DC 20036

Acoustical Society of America
Charles Schmid, Executive Director
500 Sunnyside Blvd., Woodbury, NY 11797-2999

The Society of Rheology
Andrew M. Kraynik, Secretary
Department 1512
Sandia National Labs.
Albuquerque, NM 87185

American Association of Physics Teachers
Bernard V. Khoury, Executive Officer
One Physics Ellipse
College Park, MD 20740-3845

American Crystallographic Association
William L. Duax, Executive Officer
P.O. Box 96, Endicott Station
Buffalo, NY 14205-0096

American Astronomical Society
Peter B. Boyce, Executive Officer
1630 Connecticut Avenue, N.W.
Washington, DC 20009

American Association of Physicists in Medicine
Sal Trofi, Executive Director
One Physics Ellipse
College Park, MD 20740-3846

American Vacuum Society
William D. Westwood, Secretary
Bell-Northern Research, Ltd.
P.O. Box 3511, Station C
Ottawa, Ontario K1Y 4H7, Canada

American Geophysical Union
A. F. Spilhaus, Jr., Executive Director
1630 Connecticut Avenue, N.W.
Washington, DC 20009

Affiliated Societies

American Institute of Aeronautics and Astronautics, American Meteorological Society, American Nuclear Society, ASM International, Astronomical Society of the Pacific, Division of Physical Chemistry of ACS, Engineering Information, Inc., The Geological Society of America, Instrument Society of America, International Association of Mathematical Physicists, International Centre for Diffraction Data, Materials Research Society, Microscopy Society of America, Nuclear and Plasma Sciences Society of IEEE, Physics/Astronomy Section of the Council on Undergraduate Research, Physics Section of AAAS, Society for Applied Spectroscopy, SPIE—The International Society for Optical Engineering.

Corporate Associates: Approximately 175 leading corporations, by their membership, participate in and contribute to the support of AIP.

Publications

Physical Review A · Bernd Crasemann, *Editor*, Physics Dept., University of Oregon, Eugene, OR 97403
Physical Review B · P.D. Adams, *Editor*, The American Physical Society, 1 Research Rd., Box 1000, Ridge, NY 11961
Physical Review C · Sam Austin, *Editor*, Cyclotron Labs., Michigan State University, E. Lansing, MI 48824
Physical Review D · Lowell S. Brown and D.L. Nordstrom, *Editors*, APS, 1 Research Rd., Box 1000, Ridge, NY 11961
Physical Review E · Irwin Oppenheim, *Editor*, Dept. of Chemistry, Massachusetts Institute of Technology, Cambridge, MA 02139
Physical Review Abstracts · Reid Terwilliger, *Editor*, APS, One Physics Ellipse, College Park, MD 20740-3844
Physical Review Letters · J. Sandweiss, G. Basbas, S.G. Brown, and G.L. Wells, *Editors*, APS
APS News · Brian Schwartz, *Editor*, APS, One Physics Ellipse, College Park, MD 20740-3844
Bulletin of The American Physical Society · Brian Schwartz, *Editor*, APS, One Physics Ellipse, College Park, MD 20740-3844
Reviews of Modern Physics · David Pines, *Editor*, Loomis Lab. of Physics, 1110 W. Green St., Urbana, IL 61801
The Journal of the Acoustical Society of America · Daniel W. Martin, *Editor-in-Chief*, 7349 Clough Pike, Cincinnati, OH 45244
American Journal of Physics · Robert H. Romer, *Editor*, 222 Merrill Science Bldg., Box 2262, Amherst College, Amherst, MA 01002
The Astronomical Journal · Paul W. Hodge, *Editor*, Astronomy Dept. FM-20, University of Washington, Seattle, WA 98195
Publications of the Astronomical Society of the Pacific · Howard E. Bond, *Editor*, Space Telescope Science Institute, Baltimore, MD 21218
Bulletin of the American Astronomical Society · Peter B. Boyce, *Editor*, AAS
The Astrophysical Journal · Helmut A. Abt, *Managing Editor*, Kitt Peak National Observatory, Box 26732, Tucson, AZ 85726
The Journal of Chemical Physics · J.C. Light, *Editor*, James Franck Institute, The University of Chicago, Chicago, IL 60637
Journal of Mathematical Physics · Roger G. Newton, *Editor*, Indiana Univ., The Poplars, Rm. 324, Bloomington, IN 47405
Physics of Fluids · A. Acrivos, *Editor*, The Levich Institute, Steinman 202, CCNY, Convent Ave. at 140 St., New York, NY 10031
Physics of Plasmas · Ronald C. Davidson, *Editor*, Plasma Phys. Lab., Princeton Univ., P.O. Box 451, Princeton, NJ 08543
Journal of Applied Physics · Steven J. Rothman, *Editor*, Argonne Natl. Lab., Box 8296, Argonne, IL 60439-8296
Applied Physics Letters · Hartmut Wiedersich, *Editor*, Argonne Natl. Lab., Box 8296, Argonne, IL 60439-8296
Review of Scientific Instruments · Thomas H. Braid, *Editor*, Argonne Natl. Lab., Box 8293, Argonne, IL 60439-8293
Journal of Physical and Chemical Reference Data · Jean W. Gallagher, *Editor*, NIST, MS221/A3223, Gaithersburg, MD 20899
Physics Today · Gloria B. Lubkin, *Editor*, AIP, One Physics Ellipse, College Park, MD 20740-3843
Computers in Physics · Lewis Holmes, *Editor*, One Physics Ellipse, College Park, MD 20740-3843
Chaos · David K. Campbell, *Editor*, Dept. of Physics, University of Illinois—UC, Urbana, IL 61801
Journal of Vacuum Science and Technology A · Gerald Lucovsky, *Editor*, Dept. of Physics, N. Carolina State Univ., Raleigh, NC 27650
Journal of Vacuum Science and Technology B · Gary E. McGuire, *Editor*, MCNC, Research Triangle Park, NC 27709
Surface Science Spectra · C. E. Bryson, *Editor*, Surface/Interface, Inc., Mountain View CA 94041; Gary McGuire, *Editor*, MCNC, NC 27709
Medical Physics · J.S. Laughlin, *Editor*, Memorial Sloan-Kettering Cancer Center, 1275 York Ave., New York, NY 10021
Noise Control Engineering Journal · Alan H. Marsh, *Editor-in-Chief*, DyTec Engineering, Inc., 5092 Tasman Dr., Huntington Beach, CA 92649
Powder Diffraction · Deane K. Smith, *Editor-in-Chief*, Dept. of Geosci. and Mineralogy, Penn State Univ., University Park, PA 16802
AAPT Announcer · Bernard V. Khoury, *Editor*, AAPT, One Physics Ellipse, College Park, MD 20740-3845
The Physics Teacher · Clifford E. Swartz, *Editor*, Phys. Dept., State University of New York, Stony Brook, NY 11794
Journal of Rheology · Arthur B. Metzner, *Editor*, Dept. of Chemical Engineering, University of Delaware, Newark, DE 19716
Journal of the Optical Society of America A · Bahaa E. A. Saleh, *Editor*, 2010 Massachusetts Ave., N.W., Washington, DC 20036
Journal of the Optical Society of America B · Paul F. Liao, *Editor*, 2010 Massachusetts Ave., N.W., Washington, DC 20036
Applied Optics · William T. Rhodes, *Editor-in-Chief*, Dept. of Electr. & Computer Eng., Univ. of Colorado, Boulder, CO 80309-0425
Optics Letters · Peter W. E. Smith, *Editor*, Bellcore, 331 Newman Springs Rd., Red Bank, NJ 07701
Optics and Photonics News · Andrea Pendleton, *Editor*, 2010 Massachusetts Ave., N.W., Washington, DC 20036
Journal of Lightwave Technology · Donald B. Keck, *Editor*, Corning Glass Works, Sullivan Park FR29, Corning, NY 14830
The Journal of Undergraduate Research in Physics · R.E. Adelberger, *Editor*, Physics Dept., Guilford College, Greensboro, NC 27410

Current Physics Index (CPI), quarterly and annual subject index with abstracts to all the above journals.
General Physics Advance Abstracts (GPAA), semimonthly advance abstracts of AIP-published physics literature.
Searchable Physics Information Notices (SPIN), monthly computer-readable tape of abstracts.
Current Physics Microform (CPM), monthly microfilm edition of all the above journals.
Current Physics Reprints (CPR), on-demand copies of any article in any of the above journals.
Physics Briefs (PB), semimonthly comprehensive index with abstracts to the world literature of physics.
PINET, an online physics information network.

Governing Board 1994–1995

Roland W. Schmitt, *Chair**
Reuben E. Alley
Benjamin Bederson
Roger A. Bell
Marc H. Brodsky (*ex officio*)*

Also Available:

Sample Copies

Sample copies are available to institutions considering a subscription.

Back Volumes

Back volumes are available in print, microfilm or microfiche.

Microform

Journals marked with an asterisk are available on microfilm and microfiche.

Special Discount Rates

Reduced rates are available for a variety of combination subscriptions. For details, contact AIP Circulation and Fulfillment.

Document Delivery

Obtain full-text copies of individual articles from core journals in physics – plus AIP and Member Society books and conference proceedings – through **Articles in Physics**. Documents are sent to you within 24 hours of your order via fax, mail or overnight express. For more information or to order call 1-800-480-PHYS or 415-259-5002. FAX: 415-259-5044. E-Mail: articles@aip.org

Online Access

Abstracts of journals published by AIP and Member Societies are available online in the SPIN database via the commercial service Dialog as well as on PINET, the AIP online information service. PINET also offers a current awareness database, **Advance Abstracts**, offering abstracts up to three months prior to their journal publication dates. Please call 516-576-2262 for additional information.

Book Program

AIP publishes a full line of monographs, proceedings, texts, and references. For further information in the U.S. and Canada contact William Phillips, Books Customer Service, at (516) 576-2411. Elsewhere, contact Susan Harrison, Oxford University Press, at +44 865-56767
